THE FUNDAMENTALS OF ANATOMY & PHYSIOLOGY

booksmedicos.org

MARTINI NATH BARTHOLOMEW

Spotlight Figures

1-2 Levels of Organization

2-4 Chemical Notation

3-1 Anatomy of a Model Cell **3-7** Protein Synthesis, Processing, and Packaging **3-22** Overview of Membrane Transport
3-23 Stages of a Cell's Life Cycle **3-24** DNA Replication

4-21 Inflammation and Regeneration

5-3 The Epidermis

6-11 Endochondral Ossification **6-17** Types of Fractures and Steps in Repair

7-4 Sectional Anatomy of the Skull

8-14 Sex Differences in the Human Skeleton

9-2 Joint Movement

10-10 Events at the Neuromuscular Junction **10-11** Excitation-Contraction Coupling
10-12 The Contraction Cycle and Cross-Bridge Formation

11-3 Muscle Action

12-8 Processes that Produce the Resting Membrane Potential **12-13** Generation of an Action Potential
12-14 Propagation of an Action Potential

13-8 Structure, Function, and the Peripheral Distribution of Spinal Nerves ($T_1 - L_2$) **13-14** Spinal Reflexes

14-4 Formation and Circulation of Cerebrospinal Fluid

15-8 Somatic Sensory Pathways

16-2 The Autonomic Nervous System

17-2 Olfaction and Gustation **17-13** Refractive Problems **17-16** Photoreception

18-2 Structural Classification of Hormones **18-3** G Proteins and Second Messengers
18-18 Diabetes Mellitus **18-20** The General Adaptation Syndrome

19-1 The Composition of Whole Blood **19-8** Hemolytic Disease of the Newborn

20-9 Heart Disease and Heart Attacks **20-13** Cardiac Arrhythmias

21-33 Congenital Heart Problems

22-21 Cytokines of the Immune System

23-13 Pulmonary Ventilation **23-25** Control of Respiration

24-15 The Regulation of Gastric Activity **24-27** The Chemical Events of Digestion

25-4 The Electron Transport Chain and ATP Formation **25-10** Absorptive and Postabsorptive States

26-16 Summary of Juxtamedullary Nephron Function

27-18 The Diagnosis of Acid-Base Disorders

28-12 Hormonal Regulation of Male Reproduction **28-24** Hormonal Regulation of Female Reproduction

29-5 Extra-embryonic Membranes and Placenta Formation

Pearson's Commitment to Diversity, Equity, and Inclusion

Pearson is dedicated to creating bias-free content that reflects the diversity, depth, and breadth of all learners' lived experiences.

We embrace the many dimensions of diversity, including but not limited to race, ethnicity, gender, sex, sexual orientation, socioeconomic status, ability, age, and religious or political beliefs.

Education is a powerful force for equity and change in our world. It has the potential to deliver opportunities that improve lives and enable economic mobility. As we work with authors to create content for every product and service, we acknowledge our responsibility to demonstrate inclusivity and incorporate diverse scholarship so that everyone can achieve their potential through learning. As the world's leading learning company, we have a duty to help drive change and live up to our purpose to help more people create a better life for themselves and to create a better world.

Our ambition is to purposefully contribute to a world where:

- Everyone has an equitable and lifelong opportunity to succeed through learning.
- Our educational content accurately reflects the histories and lived experiences of the learners we serve.
- Our educational products and services are inclusive and represent the rich diversity of learners.
- Our educational content prompts deeper discussions with students and motivates them to expand their own learning (and worldview).

Accessibility

We are also committed to providing products that are fully accessible to all learners. As per Pearson's guidelines for accessible educational Web media, we test and retest the capabilities of our products against the highest standards for every release, following the WCAG guidelines in developing new products for copyright year 2022 and beyond.

You can learn more about Pearson's commitment to accessibility at

<https://www.pearson.com/uk/accessibility.html>

Contact Us

While we work hard to present unbiased, fully accessible content, we want to hear from you about any concerns or needs with this Pearson product so that we can investigate and address them.

Please contact us with concerns about any potential bias at

Text and Illustration Team

Frederic (Ric) H. Martini, Ph.D.

Author

Dr. Martini received his Ph.D. from Cornell University in comparative and functional anatomy for work on the pathophysiology of stress. In addition to professional publications that include journal articles and contributed chapters, technical reports, and magazine articles, he is the lead author of 10 undergraduate texts on anatomy and physiology. He has also published books on tropical islands, on WWII history, and in science fiction. Dr. Martini has a long-standing bond with the Shoals Marine Laboratory, a joint venture between Cornell University and the University of New Hampshire, where he received his undergraduate degree. He has been active in the Human Anatomy and Physiology Society (HAPS) for over 30 years and was a member of the committee that established the course curriculum guidelines for A&P. He is a President Emeritus of HAPS after serving as President-Elect, President, and Past-President over 2005–2007. Dr. Martini is also a member of the American Physiological Society, the American Association of Anatomists, the International Society of Vertebrate Morphologists, and the Society of Military History.

Judi L. Nath, Ph.D.

Author

Dr. Judi Nath is an adjunct teaching professor at Penn State University and biology professor emerita at Lourdes University. She teaches both undergraduate and graduate students in courses including anatomy, physiology, pathophysiology, medical terminology, and science writing. She received her bachelor's and master's degrees from Bowling Green State University, which included study abroad at the University of Salzburg in Austria. Her doctoral work focused on autoimmunity, and she completed her Ph.D. from the University of Toledo. Dr. Nath is devoted to her students and strives to convey the intricacies of science in captivating ways that are meaningful, interactive, and exciting. She has won the Faculty Excellence Award—an accolade recognizing effective teaching, scholarship, and community service—multiple times and in 2013 was named as an Ohio Memorable Educator. She is active in many professional organizations, notably the Human Anatomy and Physiology Society (HAPS), where she is a past president and has served several terms on the board of directors. She is also the 2021

recipient of the HAPS President's Medal. Dr. Nath is a coauthor of *Visual Anatomy & Physiology*, *Visual Essentials of Anatomy & Physiology*, *Anatomy & Physiology*, and *Human Anatomy* (published by Pearson); she is the sole author of *Using Medical Terminology*, *Stedman's Medical Terminology*, and *Short Course in Medical Terminology* (published by Jones & Bartlett); *Applied Pathophysiology* (published by Lippincott), and *Digesting Foods and Fads and Sins Against Science* (published by McFarland). She is also a board member of America Cares for Ukrainian Children. In 2015, she and her husband established the Nath Science Scholarship at Lourdes University to assist students pursuing science-based careers. She is an aspiring tap dancer and dog trainer with goals of achieving a healthy work-life balance.

Edwin F. Bartholomew, M.S.

Author

Edwin F. Bartholomew received his undergraduate degree from Bowling Green State University and his M.S. from the University of Hawaii. Mr. Bartholomew has taught human anatomy and physiology at both the secondary and undergraduate levels. In addition, he has taught courses ranging from botany to zoology at Maui Community College (now the University of Hawaii Maui College). For 17 years, he taught at historic Lahainaluna High School, the oldest high school west of the Rockies, where he assisted in establishing a Health Occupations Students of America (HOSA) chapter. He is a coauthor of *Fundamentals of Anatomy & Physiology*, *Visual Anatomy & Physiology*, *Essentials of Anatomy & Physiology*, *Visual Essentials of Anatomy & Physiology*, *Structure and Function of the Human Body*, and *The Human Body in Health and Disease* (all published by Pearson). Mr. Bartholomew is a member of the Human Anatomy and Physiology Society (HAPS), the National Association of Biology Teachers, the National Science Teachers Association, the American Association for the Advancement of Science, and Lahaina Arts Society. He enjoys painting in oil, watercolor, and pastels, as well as growing tropical fish, aquarium plants, and orchids.

William C. Ober, M.D.

Art Coordinator and Illustrator

Dr. Ober received his undergraduate degree from Washington and Lee University and his M.D. from the University of Virginia. He also studied in the Department of Art as Applied to

Medicine at Johns Hopkins University. After graduation, Dr. Ober completed a residency in Family Practice and later was on the faculty at the University of Virginia in the Department of Family Medicine and in the Department of Sports Medicine. He also served as Chief of Medicine of Martha Jefferson Hospital in Charlottesville, Virginia. Most recently he was Visiting Professor of Biology at Washington and Lee University, where he taught courses in biological illustration and led student trips to the Galápagos Islands. He was on the Core Faculty at Shoals Marine Laboratory for 24 years, where he taught biological illustration every summer. Dr. Ober has collaborated with Dr. Martini on all his textbooks in every edition.

Claire E. Ober, R.N.

Illustrator

Claire E. Ober, RN., B.A, practiced family, pediatric, and obstetric nursing before turning to medical illustration as a full-time career. She returned to school at Mary Baldwin College, where she received her degree with distinction in studio art. Following a 5-year apprenticeship, she has worked as Dr. Ober's partner in Medical & Scientific Illustration since 1986. She was on the Core Faculty at Shoals Marine Laboratory and co-taught the biological illustration course with Dr. Ober for 24 years. The textbooks illustrated by Medical & Scientific Illustration have won numerous design and illustration awards.

Preface

The Twelfth Edition of *Fundamentals of Anatomy & Physiology* is a comprehensive textbook that fulfills the needs of today's students while addressing the concerns of their teachers. We focused our attention on these questions:

- How can we make this information meaningful, manageable, and comprehensible?
- How can we ensure that issues of diversity, equity, and inclusion are met?

During the revision process, we drew upon our content knowledge, research skills, artistic talents, and years of classroom experience to make this edition the best yet.

The broad changes to this edition are presented in the **New to the Twelfth Edition** section below, and the specific changes are presented in the **Chapter-by-Chapter Changes in the Twelfth Edition** section that follows.

New to the Twelfth Edition

- We made a concerted effort to revise text and images to align with contemporary values related to diversity, equity, and inclusion. As teaching professors, authors, and humans, we strive for sensitivity to all people; as such, we deliberately addressed issues to better reflect the world in which we live. Like life itself, language is dynamic and evolving. With this edition we attempted to strike a balance between science and the language describing that science.
- Figures and figure legends were revised according to best practices for accessibility.
- Removed page references to topics previously covered.
- Changed Tips & Tools to Tips.
- All Clinical Notes have been revised and updated.
- Revised all homeostasis figures to enhance understanding.
- Revised selected Spotlights with a vertical orientation for best viewing on screens.
- Removed references to the Atlas.
- Boldfaced terms are used on the page to focus your attention on something important and to link the word to a corresponding structure in the art. Not all boldfaced terms will appear in the glossary.
- Students can access all media in the Study Area in Mastering A&P.

- Students can access 15 SmartArt Videos in the accompanying eTextbook and Study Area of Mastering A&P.

Be sure to view the
SmartArt
video for this figure.

Chapter-by-Chapter Changes in the Twelfth Edition

This annotated table of contents provides examples of revision highlights in each chapter of the Twelfth Edition. For a more complete list of changes, please contact the publisher.

Chapter 1: An Introduction to Anatomy and Physiology

- **Revised Anatomy of a Chapter section to be more useful for students**
- **Updated medical terminology section**
- **Replaced Figure 1–1 with a more meaningful student-centered image**
- **Revised Clinical Note: Diagnostic Imaging Techniques for eTextbook (images are enlarged to make scans easier to compare)**
- **Revised Spotlight Figure 1–2**

Chapter 2: The Chemical Level of Organization

- **Revised Spotlight Figure 2–4**
- **Question added to Figure 2–4**
- **Revised Figure 2–11 by adding arrows pointing at the top of pH strip rather than plain lines to differentiate it from the pH scale at the bottom**
- **Revised Figure 2–20 by putting small arrowheads with little white highlights to clearly differentiate between bond lines and leader lines. This helps make it clearer that we are pointing at the grouping, too.**
- **Revised Figure 2–23 by making a bracket instead of two separate leader lines for the active site**
- **Revised Figure 2–25 by adding “backbone” label and adding pointed arrows for a few of the labels in places where the bond rules were the same as the lead lines**
- **Revised Figure 2–26 to show bonding with carbon in adenine**

Chapter 3: The Cellular Level of Organization

- **New Clinical Case “Mohan Gets the Run”**
- **Revised Figure 3–1 separating nonmembranous organelles and membranous organelles; and the nucleus label is more prominent**
- **Revised Figures 3–10, 3–12 (corrected number of C–G H-bonds) and 3–13**
- **Revised Spotlight Figures 3–1, 3–7, 3–22, 3–23, and 3–24**

Chapter 4: The Tissue Level of Organization

- Retitled **Clinical Case to Rubber Joints**
- Revised Figure 4–2 by adding another leader line for plural cilia
- Revised **Spotlight Figure 4–21**

Chapter 5: The Integumentary System

- Revised **Spotlight Figure 5–3**
- Updated **Nips, Tucks, and Shots Clinical Note**

Chapter 6: Bones and Bone Structure (formerly called Osseous Tissue and Bone Structure)

- Revised **Spotlight Figure 6–11**
- Revised **Spotlight Figure 6–17**
- Revised Figures 6–13 and 6–16
- Deleted section on Ukrainian Chernobyl nuclear reactor incident

Chapter 7: The Axial Skeleton

- Revised **Spotlight Figure 7–4**
- Changed “costal process” to “anterior tubercle” in Figure 7–19b
- Revised **Clinical Note: Kyphosis, Lordosis, and Scoliosis** to remove language that focused on being abnormal

Chapter 8: The Appendicular Skeleton

- New **Clinical Case “Head Over Heals”**
- Revised text in Figure 8–9b
- Revised **Spotlight Figure 8–14**

Chapter 9: Joints

- Revised **Spotlight Figure 9–2**
- Revised definition of hyperextension. From a clinical perspective, hyperextension is the term used for extension of a limb beyond the normal anatomical limit. New Figure 9–3 reflects the changes.

Chapter 10: Muscle Tissue

- Revised text in Figure 10–9a
- Revised **Spotlight Figure 10–10**
- Revised **Spotlight Figure 10–11**
- Revised **Spotlight Figure 10–12**

Chapter 11: The Muscular System

- Revised **Spotlight Figure 11–3**

Chapter 12: Nervous Tissue

- Revised **Spotlight Figure 12–8**
- Revised **Spotlight Figure 12–13**
- Revised **Spotlight Figure 12–14**
- Added hyphen so term now reads “blood-brain barrier”

Chapter 13: The Spinal Cord, Spinal Nerves, and Spinal Reflexes

- Revised **Spotlight Figure 13–8**
- Revised Figure 13–11b: changed “Nerve to Subclavius” to “Subclavian” and “Subclavian” to “Suprascapular”
- Changed “fibular nerve” to “common fibular nerve”
- Revised **Spotlight Figure 13–14**

Chapter 14: The Brain and Cranial Nerves

- New **Clinical Case “The Bells!”**
- Revised **Spotlight Figure 14–4**
- Revised Figure 14–5 regarding thalamus

- Revised Figure 14–8c regarding anterior/posterior orientation
- Revised Figure 14–13 adding label for “retractor” and refining figure question
- Revised text in Figure 14–17a

Chapter 15: Sensory Pathways and the Somatic Nervous System

- Changed “pacinian” to “Pacinian”
- Revised Figure 15–5
- Revised **Spotlight Figure 15–8**
- Removed reference to Stephen Hawking in **Clinical Note on amyotrophic lateral sclerosis**

Chapter 16: The Autonomic Nervous System and Higher-Order Functions

- Revised Figure 16.1 to represent skeletal muscle with a skeletal muscle fiber
- Revised **Spotlight Figure 16.2**
- Changed “amyloid (A) protein” to “serum amyloid A protein”

Chapter 17: The Special Senses

- Revised **Spotlight Figure 17–2**
- Removed “umami” leader and label in Figure 17–3a
- Revised **Spotlight Figure 17–13**
- Revised **Spotlight Figure 17–16**
- Changed primary term to “taste receptor cell” and secondary term to “gustatory epithelial cell”
- Switched order of Figure 17–11a and b to match orientation of Figure 17–10
- Changed term from “magnocells” to “magnocellular neurons”
- Change term from “parvo cells” to “parvocellular neurons”
- Revised Figure 17–28

Chapter 18: The Endocrine System

- Revised **Spotlight Figure 18–2**
- Revised **Spotlight Figure 18–3**
- Added “Median eminence” labels to Figures 18–6 and 18–7
- Revised **Spotlight Figure 18–18**
- Revised **Spotlight Figure 18–20**
- Changed “prostate gland” to “prostate”
- Added information on the major forms of estrogens
- Added information on adipokines
- Revised section on gamma-hydroxybutyric acid (GHB) use
- Added a new **Clinical Note on Sex and Gender**
- Revised step-art text in Figure 18–11a, number 7 within running narrative
- Changed term from “pancreatic islet cells” to “pancreatic islets”
- Revised Table 18–8, including text change from “infantile” to “congenital” and descriptions with Estrogens (females) and Androgens (males) headings

Chapter 19: Blood

- Revised definition of hematocrit
- Revised **Spotlight Figure 19–1**
- Revised Figure 19–4 by darkening reticulocyte to better reflect hemoglobin content
- Revised **Spotlight Figure 19–8**
- Removed Table 19–2
- Revised Figure 19–11 for vertical orientation

Chapter 20: The Heart

- Changed “arch of aorta” to “aortic arch”
- **Revised Spotlight Figure 20–9**
- Removed hyphen from “broken heart syndrome” Clinical Note and added “takotsubo cardiomyopathy”
- Revised QRS complex, step 5 in Figure 20–11
- **Revised Spotlight Figure 20–13**

Chapter 21: Blood Vessels and Circulation

- **Revised Spotlight Figure 21–33**
- Changed “aortic sinus” to “aortic arch” in discussion and Figure 21–13 on baroreceptor reflexes
- Changed purple arrow to blue arrow for Pulmonary circuit in Figure 21–17
- Revised Figure 21–29

Chapter 22: The Lymphatic System and Immunity

- Added section on meningeal lymphatics.
- Revised Figure 22–1
- **Revised Spotlight Figure 22–21**
- Replaced AIDS Clinical Note with a new Clinical Note on various types of vaccinations currently available

Chapter 23: The Respiratory System

- **Revised Spotlight Figure 23–13**
- **Revised Spotlight Figure 23–25**
- Added hyphen so term now reads “blood-air barrier”
- Changed V_T to V_T for tidal volume

Chapter 24: The Digestive System

- New Figure 24–4 to replace Peristalsis figure
- Changed “adult teeth” to “permanent teeth”
- **Revised Spotlight Figure 24–15**
- Changed Cirrhosis Clinical Note title to “Liver Disease”
- **Revised Spotlight Figure 24–27**

Chapter 25: Metabolism, Nutrition, and Energetics (title changed to include nutrition)

- **Revised Spotlight Figure 25–4**
- **Revised Spotlight Figure 25–10**
- Retitled 25–5 section heading
- Revised Figure 25–11

- Revised and combined Clinical Notes on Alcohol
- Revised section on brown adipose tissue (formerly called brown fat)

Chapter 26: The Urinary System

- **Revised Figure 26–11**
- **Revised Spotlight Figure 26–16**

Chapter 27: Fluid, Electrolyte, and Acid–Base Balance

- **Revised Spotlight Figure 27–18**

Chapter 28: The Reproductive System

- Revised Figure 28–8 to clarify reductional and equational meiotic divisions
- Revised Figure 28–9
- Added hyphen so term now reads “blood-testis barrier”
- **Revised Spotlight Figure 28–12**
- Revised Figure 28–21
- **Revised Spotlight Figure 28–24**
- Revised Figure 28–26
- Changed “bulb of vestibule” to “vestibular bulb”

Chapter 29: Development and Inheritance

- Changed “differentiation” to “cellular differentiation”
- **Revised Spotlight Figure 29–5**
- Added new section and new Figure 29–8 on sexual differentiation
- Figure number changes: Figure 29–8 is now Figure 29–9; Figure 29–9 is now Figure 29–10; Figure 29–10 is now Figure 29–11; Figure 29–11 is now Figure 29–12; Figure 29–12 is now Figure 29–13; Figure 29–13 is now Figure 29–14; Figure 29–14 is now Figure 29–15; Figure 29–15 is now Figure 29–16; Figure 29–16 is now Figure 29–17; Figure 29–17 is now Figure 29–18; Figure 29–18 is now Figure 29–19; and Figure 29–19 is now Figure 29–20.
- Human Genome section updated

Appendices

- Revised title of Appendix B to Gas Pressure Measurements
- Appendix C is now Turnover Time for Selected Cells
- Appendix D is now Codon Chart
- Appendix E is now The Periodic Table

Acknowledgments

This textbook represents a group effort, and we would like to acknowledge the people who worked together with us to create this Twelfth Edition.

Leading our thank you list are the instructors who offered invaluable suggestions throughout the revision process. We thank them for their participation and list their names and affiliations below.

Claudi Biggers, *Amarillo College*

Gi'Zelle Davis, *Houston Community College*

Jinger Doe, *Truckee Meadows Community College*

Lauren Gollahon, *Texas Tech University*

Ibrahim El Idrissi, *College of Staten Island*

Nathaniel King, *Palm Beach State College*

Teresa Lake, *Harper College*

Shannon Larson, *College of Southern Nevada*

Dan Lykins, *University of Colorado, Colorado Springs*

Sal Masi, *Nassau Community College*

For their work on the new SmartArt Animations and other key Mastering and eTextbook features, we would like to thank:

Janet Brodsky, *Ivy Tech Community College of Indiana*

Donna Cempa-Danziger, *Nassau Community College*

Greg Klein, *Cincinnati State and Technical College*

Mary Katherine Lockwood, *University of New Hampshire*

Tangela Marsh, *Ivy Tech Community College of Indiana*

Russell Nolan, *Baton Rouge Community College*

Saeed Rahmanian, *Roane State Community College*

Valerie Wheat, *Jefferson Community and Technical College*

Foremost, we acknowledge our friend and mentor, Ric Martini. Ric started this Martini franchise by moving swirling ideas in his head onto notebook pages, sketch pads, coffee-stained keyboards (typewriter and computer), and eventually into the book in your hands or on your screen. I (Judi) first met Ric in 1994 on the Isle of Shoals Marine Lab, where he was giving a workshop on diving physiology. Later that day, I met his wife, Kitty. From that moment, we forged an immediate friendship. Ric is a phenomenal teacher, who taught me how to be a successful author. Eventually, Ric felt comfortable enough to step back from authoring as he gradually handed over the reins to Ed and me. Were it not for Ric, I'd still be creating Kinko's course packs disguised as textbooks for my students. Thank you, Ric, for trusting us with your first-born.

No book is written and published in isolation. While authors may have their noses in the professional literature and their fingers on computer keyboards, there are many (many!)

people involved in the behind-the-scenes work before, during, and after publication. The next paragraphs attempt to express our appreciation for them.

Without exception, reviewers stressed the importance of accurate, integrated, and visually attractive illustrations in helping readers understand essential material. The revision of the art program was directed by Bill Ober, M.D., and Claire E. Ober, RN. Their suggestions about presentation sequence, topics of clinical importance, and revisions to the proposed art were of incalculable value to us and to the project.

A huge thank you to Professor Larry Young, who greatly assisted with issues related to diversity, equity, and inclusion (DEI). When I first met Larry, I knew we had to have him on our team. His experience teaching, talking, and writing about DEI, coupled with his vast knowledge in this area, is unparalleled. Moreover, he was always willing to assist any time, even when I would text or email when he least expected! Most times that played out in a series of multi-modal messaging. Like so many people associated with this book, he was a calming, knowledgeable presence.

We also express our appreciation to the editors and support staff at Pearson Science.

We owe special thanks to our Project Manager, Cheryl Cechvala, for shepherding this project from start to finish. Her ability to manage every detail with such fervor and interest is commendable. She also has an incredible command of the English language paired with exceptional oratory ability—it's always fun having candid conversations. Cheryl's calmness is a welcome reprieve whenever publishing gets hectic. We are appreciative of all her efforts on our behalf and thankful to have her leading the team.

Dapinder Dosanjh was the most careful Content Producer we have ever had the pleasure of working with. She was always available and answered every question we had with speed and accuracy. Her attention to detail is remarkable and we always appreciated her demeanor and professionalism.

Writing on tight schedules with looming deadlines is tough, but Cheryl and Dapinder ensured that the process was as smooth as possible. Our bi-monthly meetings kept morale high and the chapters flowing.

We are grateful to Joanna Dinsmore for her very careful attention to detail and consistency in her copyedit of the text and art. Additional Pearson team members carried on behind the scenes and are equally important. These people include the following:

Serina Beauparlant, Director, Product Management;

Courtney Davis, Product Marketing Manager;

Sarah Shefveland, Mathew Koul, Diandra Coles, Lucinda Bingham, Rich Media Content Producers;
Kristen Antal, Mastering Media Producer;
Cheryl Chi, Senior Content Developer;
Jan Troutt and Tim Brummett from Troutt Visual Services;
Mark Ong, Design Manager for the cover and interior designs;
Production team at Integra, including Aimee Bear, Gina Linko, and Stacey Miller;
Permissions team at Straive, including Matthew Perry, Rights & Permissions Project Manager, and Joan Diaz, Rights & Permissions Specialist;

To help improve future editions, we encourage you to send any pertinent information, suggestions, or comments about the organization or content of this textbook to us directly. We warmly welcome comments and suggestions and will carefully consider them in the preparation of the Thirteenth Edition.

Judi L. Nath
Edwin F. Bartholomew

Global Edition Acknowledgments

Pearson would like to thank the following for their contribution to the Global Edition:

Contributors for the Twelfth Edition

Richard Brooksbank, *University of the Witwatersrand*
Christiane Van den Branden, *Vrije Universiteit Brussel*

Reviewers for the Twelfth Edition

The Chemical Level of Organization 55

An Introduction to the Chemical Level of Organization 56

- 2-1 Atoms are the basic particles of matter 56**
 - Atomic Structure 56
 - Elements and Isotopes 57
 - Atomic Weights 58
 - Electrons and Energy Levels 58
- 2-2 Chemical bonds are forces formed by interactions between atoms 60**
 - Ionic Bonds 62
 - Covalent Bonds 63
 - Hydrogen Bonds 64
 - States of Matter 65
- 2-3 Decomposition, synthesis, and exchange reactions are important types of chemical reactions in physiology 65**
 - Basic Energy Concepts 65
 - Types of Chemical Reactions 66
- 2-4 Enzymes speed up reactions by lowering the energy needed to start them 67**
- 2-5 Inorganic compounds lack carbon, and organic compounds contain carbon 68**
- 2-6 Physiological systems depend on water 68**
 - The Properties of Aqueous Solutions 69
 - Colloids and Suspensions 70
- 2-7 Body fluid pH is vital for homeostasis 71**
- 2-8 Acids, bases, and salts have important physiological roles 72**
 - Acids and Bases 72
 - Salts 72
 - Buffers and pH Control 72
- 2-9 Living things contain organic compounds made up of monomers, polymers, and functional groups 73**
- 2-10 Carbohydrates contain carbon, hydrogen, and oxygen in a 1:2:1 ratio 73**
 - Monosaccharides 73
 - Disaccharides and Polysaccharides 74

- 2-11 Lipids often contain a carbon-to-hydrogen ratio of 1:2** 75
 Fatty Acids 76
 Eicosanoids 76
 Glycerides 77
 Steroids 78
 Phospholipids and Glycolipids 79
- 2-12 Proteins contain carbon, hydrogen, oxygen, and nitrogen and are formed from amino acids** 79
 Protein Structure 81
 Protein Shape 81
 Enzyme Function 83
 Glycoproteins and Proteoglycans 85
- 2-13 DNA and RNA are nucleic acids** 85
 Structure of Nucleic Acids 85

3 The Cellular Level of Organization 93

An Introduction to Cells 94

- 3-1 The plasma membrane separates the cell from its surrounding environment and performs various functions** 94
 Membrane Lipids 95
 Membrane Proteins 95
 Membrane Carbohydrates 99
- 3-2 Organelles within the cytoplasm perform particular functions** 99
 The Cytosol 100
 Nonmembranous Organelles 100
 Membranous Organelles 104
- 3-3 The nucleus contains DNA and enzymes essential for controlling cellular activities** 111
 Structure of the Nucleus 111
 Information Storage in the Nucleus 112
- 3-4 DNA controls protein synthesis, cell structure, and cell function** 113
 Regulation of Transcription by Gene Activation 113
 Transcription of DNA into mRNA 113
 Translation from mRNA into a Polypeptide 115
 How DNA Controls Cell Structure and Function 117

- 3-5 Diffusion is a passive transport mechanism that assists membrane passage of solutes and water** 118
 Diffusion 118
 Osmosis: Diffusion of Water across Selectively Permeable Membranes 121
- 3-6 Carrier-mediated and vesicular transport assist membrane passage of specific substances** 122
 Carrier-Mediated Transport 123
 Vesicular Transport 125
- 3-7 The membrane potential of a cell results from the unequal distribution of positive and negative charges across the plasma membrane** 127
- 3-8 Stages of the cell life cycle include interphase, mitosis, and cytokinesis** 130
 The Cell Life Cycle 130
 The Mitotic Rate and Energy Use 131
- 3-9 Several factors regulate the cell life cycle** 131
- 3-10 Abnormal cell growth and division characterize tumors and cancers** 135
- 3-11 Cellular differentiation is cellular specialization as a result of gene activation or repression** 137

4 The Tissue Level of Organization 142

An Introduction to the Tissue Level of Organization 143

- 4-1 The four tissue types are epithelial, connective, muscle, and nervous** 143
- 4-2 Epithelial tissue covers body surfaces, lines internal surfaces, and serves other essential functions** 143
 Functions of Epithelial Tissue 144
 Characteristics of Epithelial Tissue 145

Specializations of Epithelial Cells 145
 Maintaining the Integrity of Epithelia 146

- 4-3 Cell shape and number of layers determine the classification of epithelia 148**
 Classification of Epithelia 148
 Glandular Epithelia 150
- 4-4 Connective tissue has varied roles in the body that reflect the physical properties of its three main types 154**
- 4-5 Connective tissue proper includes loose connective tissues that fill internal spaces and dense connective tissues that contribute to the internal framework of the body 156**
 Structure of Connective Tissue Proper 156
 Loose Connective Tissues 158
 Dense Connective Tissues 161
 Fascia: Layers of Connective Tissue Proper 161
- 4-6 Blood and lymph are fluid connective tissues that transport cells and dissolved materials 163**
- 4-7 The supporting connective tissues cartilage and bone provide a strong framework 164**
 Cartilage 164
 Bone 165
- 4-8 Tissue membranes made from epithelia and connective tissue make up four types of physical barriers 168**
 Mucous Membranes 168
 Serous Membranes 168
 The Cutaneous Membrane 169
 Synovial Membranes 170
- 4-9 The three types of muscle tissue are skeletal, cardiac, and smooth 170**
 Skeletal Muscle Tissue 170
 Cardiac Muscle Tissue 172
 Smooth Muscle Tissue 172
- 4-10 Nervous tissue responds to stimuli and propagates electrical impulses throughout the body 172**
- 4-11 The response to tissue injury involves inflammation and regeneration 173**
 Inflammation 173
 Regeneration 174
- 4-12 With advancing age, tissue regeneration decreases and cancer rates increase 174**
 Aging and Tissue Structure 174
 Aging and Cancer Incidence 174

13 The Spinal Cord, Spinal Nerves, and Spinal Reflexes 461

An Introduction to the Spinal Cord, Spinal Nerves, and Spinal Reflexes 462

- 13-1 This text's coverage of the nervous system parallels its simple-to-complex levels of organization 462**
- 13-2 The spinal cord is surrounded by three meninges and has spinal nerve roots 463**
 - Gross Anatomy of the Spinal Cord 463
 - Protection of the Spinal Cord: Spinal Meninges 466
- 13-3 Spinal cord gray matter integrates information and initiates commands, and white matter carries information from place to place 468**
 - Functional Organization of Gray Matter 468
 - Functional Organization of White Matter 468
- 13-4 Spinal nerves extend to form peripheral nerves, sometimes forming plexuses along the way; these nerves carry sensory and motor information 470**
 - Anatomy of Spinal Nerves 470
 - Peripheral Distribution and Function of Spinal Nerves 470
 - Nerve Plexuses 475
- 13-5 Interneurons are organized into functional groups called neuronal pools 480**
- 13-6 The different types of neural reflexes are all rapid, automatic responses to stimuli 481**
 - The Reflex Arc 481
 - Classification of Reflexes 484
- 13-7 Monosynaptic reflexes produce simple responses, while polysynaptic reflexes can produce complex behaviors 485**
 - Monosynaptic Reflexes 485
 - Polysynaptic Reflexes 487
- 13-8 The brain can affect spinal cord-based reflexes 488**
 - Voluntary Movements and Reflex Motor Patterns 488
 - Reinforcement and Inhibition 488

Chapter Review 489

14 The Brain and Cranial Nerves 493

An Introduction to the Brain and Cranial Nerves 494

14-1 The brain develops four major regions: the cerebrum, cerebellum, diencephalon, and brainstem 494

- Major Brain Regions and Landmarks 494
- Embryology of the Brain 496
- Ventricles of the Brain 496

14-2 The brain is protected and supported by the cranial meninges, cerebrospinal fluid, and the blood-brain barrier 497

- The Cranial Meninges 497
- Cerebrospinal Fluid 499
- The Protective Function of the Cranial Meninges and CSF 501
- The Blood Supply to the Brain 501
- The Blood-Brain Barrier 501

14-3 Brainstem: The medulla oblongata relays signals between the rest of the brain and the spinal cord 502

14-4 Brainstem: The pons contains nuclei that process and tracts that relay sensory and motor information 505

14-5 Brainstem: The midbrain regulates visual and auditory reflexes and controls alertness 506

14-6 The cerebellum coordinates reflexive and learned patterns of muscular activity at the subconscious level 506

- Structure of the Cerebellum 506
- Functions of the Cerebellum 506

14-7 The diencephalon integrates sensory information with motor output at the subconscious level 509

- The Thalamus 509
- The Hypothalamus 510

14-8 The limbic system is a group of nuclei and tracts that functions in emotion, motivation, and memory 512

14-9 The cerebrum contains motor, sensory, and association areas, allowing for higher mental functions 514

- Structure of the Cerebral Cortex and Cerebral Hemispheres 514
- The White Matter of the Cerebrum 514
- The Basal Nuclei 516
- Motor, Sensory, and Association Areas of the Cortex 518
- Integrative Centers and Higher Mental Functions 520
- Monitoring Brain Activity: The Electroencephalogram (EEG) 521

14-10 Cranial reflexes are rapid, automatic responses involving sensory and motor fibers of cranial nerves 534

The Autonomic Nervous System and Higher-Order Functions 563

An Introduction to the Autonomic Nervous System and Higher-Order Functions 564

- 16-1 The autonomic nervous system, which has sympathetic and parasympathetic divisions, is involved in the unconscious regulation of visceral functions 564**
 - Comparison of the Somatic and Autonomic Nervous Systems 564
 - Organization of the ANS 565
 - Divisions of the ANS 566
- 16-2 The sympathetic division has short preganglionic fibers and long postganglionic fibers and is involved in using energy and increasing metabolic rate 566**
 - Functional Organization of the Sympathetic Division 566
 - Sympathetic Activation 571
- 16-3 Different types of neurotransmitters and receptors lead to different sympathetic effects 571**
 - Effects of Sympathetic Stimulation of Adrenergic Synapses and Receptors 572
 - Effects of Sympathetic Stimulation on Other Types of Synapses 573
- 16-4 The parasympathetic division has long preganglionic fibers and short postganglionic fibers and is involved in conserving energy and lowering metabolic rate 573**
 - Functional Organization of the Parasympathetic Division 573
 - Parasympathetic Activation 574
- 16-5 Different types of receptors lead to different parasympathetic effects 574**
 - Effects of Parasympathetic Stimulation of Cholinergic Receptors 574
 - Effects of Toxins on Cholinergic Receptors 574
- 16-6 The differences in the organization of sympathetic and parasympathetic structures lead to widespread sympathetic effects and specific parasympathetic effects 575**
 - Summary of the Sympathetic Division 576
 - Summary of the Parasympathetic Division 576
- 16-7 Dual innervation of organs allows the sympathetic and parasympathetic divisions to coordinate vital functions 576**
 - Anatomy of Dual Innervation 577
 - Autonomic Tone 579
- 16-8 Various levels of autonomic regulation allow for the integration and control of autonomic functions 579**
 - Visceral Reflexes 579
 - Higher Levels of Autonomic Control 580
 - The Integration of ANS and SNS Activities 580

- 16-9 Higher-order functions include memory and states of consciousness, and neurotransmitters influence behavior 581**

Memory 582

States of Consciousness 584

Influence of Neurotransmitters on Brain Chemistry and Behavior 586

An Introduction to Anatomy and Physiology

Learning Outcomes

These Learning Outcomes correspond by number to this chapter's sections and indicate what you should be able to do after completing the chapter.

- 1-1 ■ Describe how to use the text and art to master your learning.
- 1-2 ■ Define anatomy and physiology, explain the relationship between these sciences, and describe various specialties of each discipline.
- 1-3 ■ Identify the major levels of organization in organisms from the simplest to the most complex, and identify the major components of each organ system.
- 1-4 ■ Describe the origins of anatomical and physiological terms and explain the significance of standardizing terms.
- 1-5 ■ Use anatomical terms to describe body regions, body sections, and relative positions.
- 1-6 ■ Identify the major body cavities of the trunk and their subdivisions and describe the functions of each.
- 1-7 ■ Explain homeostasis.
- 1-8 ■ Describe how negative feedback and positive feedback are involved in homeostatic regulation.

CLINICAL CASE

Using A&P to Save a Life

An emergency medical technician (EMT) is on the way to the emergency department with a young victim of street violence. A knife with a 6-inch blade had been found next to the bleeding, unconscious man.

“We have a young male with multiple stab wounds. He has lost a lot of blood and we can barely get a blood pressure,” the EMT radios to the triage nurse in the emergency department as the ambulance squeals through traffic. “We started an IV and we are pouring in fluid as fast as we can.”

“Where are the wounds?” asks the receiving nurse.

“He has a deep wound in his right upper quadrant, just inferior to the diaphragm. I can see bruising from the hub of the knife around the wound, and there is another wound in his anterior

right thigh. His pulse is 120 and thready (weak). His blood pressure is 60 over 30.”

“How long has he been down?” questions the nurse.

“Less than a half hour. We intubated him (inserted a breathing tube) and started a large-bore IV as soon as we got there. We are 10 minutes out now.”

“Keep the fluids going wide open, keep pressure on the thigh, and take him directly to Trauma Room 1,” come the instructions. Meanwhile, the nurse orders the trauma team to Trauma Room 1, orders X-Ray to be

on standby in the room, and requests 4 units of type O negative whole blood—the universal donor blood—from the blood bank.

Will the team be ready to save this young man? To find out, turn to the Clinical Case Wrap-Up at the end of the chapter.

An Introduction to Studying the Human Body

Welcome to the field of human anatomy and physiology—known simply as A&P! In this textbook, we introduce the inner workings of the human body, giving information about both its structure (anatomy) and its function (physiology). Many students who use this book are preparing for jobs in health-related fields; but regardless of career choice, the information within these pages is relevant to your future.

We focus on the human body, but the principles learned also apply to other living things. Our world contains an enormous diversity of living organisms, which vary widely in appearance and environment. One aim of *biology*—the study of life—is to discover the unity and the patterns that underlie this diversity. As we study human anatomy and physiology, three main concepts emerge: (1) the principle of complementarity of structure and function, (2) the hierarchy of structural relationships, and (3) homeostasis, the tendency toward internal balance. These principles are the foundation for learning about human organisms.

Before we begin with the science of human anatomy and physiology, let's turn our attention to the science of learning and learning strategies. To make the most of your learning experience, apply these strategies, which were collected from educational research.

1-1 To make the most of your learning, read the text and view the art together

Learning Outcome Describe how to use the text and art to master your learning.

Getting to Know Your Textbook

This first section of the book sets the stage for your success in this course and introduces you to the basic principles of learning. Just as there are three underlying concepts in A&P, there are two basic principles to using your textbook effectively to learn A&P. Practicing these principles helps you throughout your college career.

Let's start. Think back to your first childhood book. You most likely began with a “picture book.” Then, as you learned the alphabet and developed speech, you progressed to “word books.” The next step was “chapter books.” Somewhere along the way, you quit looking at pictures and focused solely on the words (text). Maybe the shift in focus to text-based reading without looking at the pictures happened in high school. You began reading words—paragraph upon paragraph, page upon page of words. Now, you are in college, and we need to realign your focus.

In college, you are faced with lots of new terms, abstract concepts, and unfamiliar images. That's great, because college is intended to increase your knowledge and expand your horizons. However, educational research has shown that undergraduate students tend to simply read the text (also called the *narrative*), without paying attention to the pictures (visuals, art, photos, diagrams, illustrations, figures, images, and tables). While you can certainly learn from this approach, further research shows that when students *read the text and then look at the corresponding picture, they learn the material better!*

Although this may sound quite intuitive, most students do not do that. So, we wrote a book that truly integrates text with art to help you learn A&P. Please continue reading as we walk you through the process of using a textbook to enhance your

learning. Much of what we're about to tell you applies to most of your college textbooks, but we'll focus on this book, since it was written for students such as you.

Anatomy of a Chapter

Your book is broken down into *sections* with *text–art integration* and specific *learning outcomes* for each section. A **section** is a unit about a topic that continues to build on previously learned topics. The sectional layout promotes logical, efficient navigation through the material, while callouts to figures integrate the text with the art. **Text–art integration** implies that the figures are close to the lines of text and that the figure legends are adjacent to the art. Look at that figure when you see a callout for it. The figure callouts look like this: (**Figure 1–1**). They are color-coded on purpose so you can stop reading, look at the figure, and then find your place again when you go back to reading the text. So, *strategy #1 is to read the text and then study the image that goes along with the narrative.*

Learning outcomes are educational objectives that use key verbs and target specific knowledge or skills you should achieve. The learning outcomes appear at the beginning of each chapter and within the chapter under the sentence-based headings. *Strategy #2 is to pay attention to these learning outcomes because they are tied directly to testing and tell you what you should be able to do after reading that specific section and studying the images.*

The third strategy links your book with instruction. It's likely you have these same questions and thoughts as the student in **Figure 1–1**. *Strategy #3 is to communicate with your instructor, pay*

attention to the course syllabus, stay on top of your reading and assignments, and use the study tools available to you. Perhaps you can find comfort knowing that millions of students just like you have successfully completed anatomy and physiology courses.

✓ Checkpoint

1. Describe a learning outcome.
2. Explain how to use your textbook most effectively to enhance your learning.

See the blue Answers tab at the back of the book.

1-2 Anatomy (structure) and physiology (function) are closely integrated

Learning Outcome Define anatomy and physiology, explain the relationship between these sciences, and describe various specialties of each discipline.

Anatomy is the study of internal and external body structures and their physical relationships among other body parts. In contrast, **physiology** is the study of how living organisms perform their vital functions. Someone studying anatomy might, for example, examine where a particular muscle attaches to the skeleton. Someone studying physiology might consider how a muscle contracts or what forces a contracting muscle exerts on the skeleton. You are studying both anatomy and physiology in this text, so let's look at the relationships between these sciences.

Figure 1–1 Getting Ready for Learning Anatomy and Physiology.

Anatomy and physiology are closely integrated, both in theory and practice. Anatomical information provides clues about functions, and physiological processes can be explained only in terms of the underlying anatomy. This is a very important concept in living systems:

1

All specific functions are performed by specific structures, and the form of a structure relates to its function. This is known as the *principle of complementarity of structure and function*.

The link between structure and function is always present, but not always understood. For example, the anatomy of the heart was clearly described in the 15th century, but almost 200 years passed before the heart's pumping action was demonstrated.

Anatomists and physiologists approach the relationship between structure and function from different perspectives. To understand the difference, suppose you asked an anatomist and a physiologist to examine a gas-powered car and report their findings. The anatomist might begin by measuring and photographing the various parts of the car and, if possible, taking it apart and putting it back together. The anatomist could then explain its key *structural relationships*—for example, how the pistons are seated in the engine cylinders, how the crankshaft is connected to the pistons, and how the transmission links the drive shaft to the axles and, thus, to the wheels. The physiologist also would note the relationships among the car's parts, but they would focus mainly on its *functional* characteristics, such as how the combustion of gasoline in the cylinders moves the pistons up and down and makes the drive shaft rotate, and how the transmission conveys this motion to the axles and wheels so that the car moves. Additionally, the physiologist might also study the amount of power that the engine could generate and the amount of force transmitted to the wheels in different gears.

Our basic approach in this textbook is to start with the descriptive anatomy of body structures (appearance, size, shape, location, weight, and color) before considering the related functions. Sometimes the groups of organs that make up an *organ system* perform very diverse functions, and in those cases, we consider the functions of each individual organ separately. A good example is our discussion of the digestive system and its organs. You can learn about the functions of the salivary glands in one section, and the functions of the tongue in another. In other systems, the organs work together so extensively that we present an overall discussion of their physiology, after we describe the system's anatomy. The lymphatic system (which contains a network of vessels) and the cardiovascular system, for example, are treated using this approach.

Anatomy

When a person looks at something, how far away they are from it often determines what they see. You get a very different view of your neighborhood from a satellite photo than from your front yard. Similarly, the method of observation has a dramatic effect on personal understanding of the structure of the human body. Based on the degree of structural detail being considered,

we divide **human anatomy**, the study of the structure of the human body, into *gross anatomy* and *microscopic anatomy*.

Gross Anatomy

Gross anatomy, or *macroscopic anatomy*, involves examining fairly large structures. Gross anatomy (from the Latin term *grossus*, meaning “thick” or “massive”) is done without using a microscope and can involve the study of anatomy by dissecting a cadaver. There are many different forms of gross anatomy:

- *Surface anatomy*, or superficial anatomy, is the study of the general form of the body's surface, especially in relation to its deeper parts.
- *Regional anatomy* focuses on the anatomical organization of specific body areas, such as the head, neck, or trunk. Many advanced anatomy courses stress a regional approach, because it emphasizes the spatial relationships among structures already familiar to students.
- *Sectional anatomy* is the study of the relationship of the body's structures by examining cross sections of the tissue or organ.
- *Systemic anatomy* is the study of the structure of *organ systems*, which are groups of organs that function together in a coordinated manner. Examples include the *skeletal system*, composed primarily of bones; the *muscular system*, made up of skeletal muscles; and the *cardiovascular system*, consisting of the heart, blood, and vessels. We take a systemic anatomy approach in this book because this format works well for clarifying functional relationships among the component organs. We introduce the 11 organ systems in the human body later in the chapter.
- *Clinical anatomy* includes several subspecialties important in clinical practice. Examples include *pathological anatomy* (anatomical features that change during illness), *radiographic anatomy* (anatomical structures seen using specialized imaging techniques), and *surgical anatomy* (anatomical landmarks important in surgery).
- *Developmental anatomy* describes the changes in form that take place from fertilization through adulthood. The techniques of developmental anatomists are similar to those used in gross anatomy and in microscopic anatomy (discussed next) because developmental anatomy considers anatomical structures over a broad range of sizes—from a single cell to an adult human. The most extensive structural changes take place during the first 2 months of development. The study of these early developmental processes is called **embryology** (em-brĒ-OL-ō-jĒ).

Microscopic Anatomy

Microscopic anatomy deals with structures that we cannot see without magnification. The boundaries of microscopic anatomy are set by the limits of the equipment we use. With a dissecting microscope, tissue structure is seen. With a light

Clinical Note *Habeas Corpus* (“You Shall Have the Body”)

It is the first day of anatomy class. Students await the arrival of their white-coated and gloved professor. Anxiety mounts as a stretcher covered in surgical drapes is wheeled in. This is the cadaver. Who will faint? *Will it be me?* For many students in the health professions, cadaver dissection is a cornerstone of their training. These students are following in a revered tradition that began 2300 years ago with the first examinations of the body after death by Greek royal physicians. The expression “a skeleton in your closet” dates from a later era when medical students had to procure bodies on their own for study (and keep them hidden in the closet). There is much to be learned from death. Cadaver dissections also reveal much about life. After working closely on a cadaver for months,

students develop an attachment to “their” body, often respectfully naming it. The intimate revelations of the scalpel, the highly personal variations of human anatomy, the Rubik’s cube of disease, and the stark reality of death combine to leave a deep intellectual and emotional mark on students. Students and faculty may end the course with a ceremony to pay their respects to this human body and to this privileged experience.

1

microscope, basic details of cell structure are visible. And with an electron microscope, individual molecules that are only a few nanometers (billionths of a meter) across can be seen.

Microscopic anatomy includes two major subdivisions: cytology and histology. **Cytology** (sī-TOL-ō-jē) is the study of the internal structure of individual *cells*, the simplest units of life. Cells are made up of chemical substances in various combinations, and our lives depend on the chemical processes that take place in the trillions of cells in the body. For this reason, we consider basic chemistry (Chapter 2) before we examine cell structure (Chapter 3). **Histology** (his-TOL-ō-jē) is the examination of *tissues*—groups of specialized cells that work together to perform specific functions (Chapter 4). Tissues combine to form *organs*, such as the heart, kidney, liver, or brain, each with specific functions. Many organs are easy to examine without a microscope, so at the organ level we cross the boundary from microscopic anatomy to gross anatomy. As we proceed through the text, we consider details at all levels, from microscopic to macroscopic.

Physiology

Human physiology is the study of the functions, or workings, of the human body. These functions are complex processes and much more difficult to examine than most anatomical structures. As a result, there are even more specialties in physiology than in anatomy. Examples include the following:

- *Cell physiology*, the study of the functions of cells, is the cornerstone of human physiology. Cell physiology looks at the chemistry of the cell. It includes both chemical processes within cells and chemical interactions among cells.
- *Organ physiology* is the study of the function of specific organs. An example is *cardiac physiology*, the study of heart function—how the heart works.
- *Systemic physiology* includes all aspects of the functioning of specific organ systems. Cardiovascular physiology, respiratory physiology, and reproductive physiology are examples.

- *Pathological physiology* is the study of the effects of diseases on organ functions or system functions. Modern medicine depends on an understanding of both normal physiology and pathological physiology.

Physicians normally use a combination of anatomical, physiological, chemical, and psychological information when they evaluate patients. When a patient presents with **signs** (objective disease indications like a fever) and **symptoms** (subjective disease indications, such as tiredness), the physician will look at the structures affected (gross anatomy), perhaps collect a fluid or tissue sample (microscopic anatomy) for analysis, and ask questions to find out what changes from normal functioning the patient is experiencing. Think back to your last trip to a doctor’s office. Not only did the physician examine your body, noting any anatomical abnormalities, but they also evaluated your physiological processes by asking questions, observing your movements, listening to your body sounds, taking your temperature, and perhaps requesting chemical analyses of fluids such as blood or urine.

In evaluating all these observations to reach a diagnosis, physicians rely on a logical framework based on the scientific method. The **scientific method** is a system of advancing knowledge that begins with careful observation, proposing a hypothesis from the observation, and then testing that hypothesis through experimentation. This method is at the core of all scientific thought, including medical diagnosis.

Checkpoint

3. **Define anatomy.**
4. **Define physiology.**
5. **Describe how anatomy and physiology are closely related.**
6. **What is the difference between gross anatomy and microscopic anatomy?**
7. **Identify several specialties of physiology.**
8. **Why is it difficult to separate anatomy from physiology?**

See the blue Answers tab at the back of the book.

1-3 Levels of organization progress from chemicals to a complete organism

Learning Outcome Identify the major levels of organization in organisms from the simplest to the most complex, and identify the major components of each organ system.

1

Our understanding of how the human body works is based on investigations of its different levels of organization. Higher levels of organization are more complex and more variable than lower levels. Chapters 2, 3, and 4 consider the chemical, cellular, and tissue levels of organization of the human body. These levels are the foundations of more complex structures and vital processes, as we describe in Chapters 5–29. The six levels of organization of the human body are shown in **Spotlight Figure 1–2** and include:

- **The Chemical Level.** **Atoms** are the smallest stable units of matter. They can combine to form **molecules** with complex shapes. The atomic components and unique three-dimensional shape of a particular molecule determine its function. For example, complex protein molecules form filaments that produce the contractions of heart muscle cells. We explore this level of organization in Chapter 2.
- **The Cellular Level.** **Cells** are the smallest living units in the body. Complex molecules can form various types of larger structures called *organelles*. Each organelle has a specific function in a cell. Energy-producing organelles provide the energy needed for heart muscle cell contractions. We examine the cellular level of organization in Chapter 3.
- **The Tissue Level.** A **tissue** is a group of cells working together to perform one or more specific functions. Heart muscle cells, also called cardiac muscle cells (*cardium*, heart), interact with other types of cells and with materials outside the cell to form cardiac muscle tissue. We consider the tissue level of organization in Chapter 4.
- **The Organ Level.** **Organs** are made of two or more tissues working together to perform specific functions. Layers of cardiac muscle tissue, in combination with another type of tissue called connective tissue, form the bulk of the wall of the heart, which is a hollow, three-dimensional organ.
- **The Organ System Level.** A group of organs interacting for a particular function forms an **organ system**. Each time the heart contracts, for example, it pushes blood into a network of blood vessels. Together, the heart, blood, and blood vessels make up the cardiovascular system, one of 11 organ systems in the body. This system functions to distribute oxygen and nutrients throughout the body.
- **The Organism Level.** An individual life form is an **organism**. In our case, an individual human is the highest level of organization that we consider. All body organ systems must work together to maintain the life and health of the organism.

The organization at each level determines not only the structural characteristics but also the functions of higher levels. For example, the arrangement of atoms and molecules at the chemical level creates the protein filaments and organelles at the cellular level that give individual cardiac muscle cells the ability to contract. At the tissue level, these cells are linked, forming cardiac muscle tissue. The structure of the tissue ensures that the contractions are coordinated, producing a powerful heartbeat. When that beat occurs, the internal anatomy of the heart, an organ, enables it to function as a pump. The heart is filled with blood and connected to blood vessels, and its pumping action circulates blood through the vessels of the cardiovascular system. Through interactions with the respiratory, digestive, urinary, and other systems, the cardiovascular system performs a variety of functions essential to organism survival.

Something that affects a system will ultimately affect each of the system's parts. For example, after massive blood loss, the heart cannot pump blood effectively. When the heart cannot pump and blood cannot flow, oxygen and nutrients cannot be distributed to the heart or around the body. Very soon, the cardiac muscle tissue begins to break down as individual muscle cells die from oxygen and nutrient starvation. These changes will not be restricted to the cardiovascular system. All cells, tissues, and organs in the body will be damaged. **Spotlight Figure 1–2** illustrates the levels of organization and introduces the 11 interdependent, interconnected organ systems in the human body.

The cells, tissues, organs, and organ systems of the body coexist in a relatively small, shared environment, much like the residents of a large city. Just as city dwellers breathe the same air and drink the water supplied by the local water company, cells in the human body absorb oxygen and nutrients from the fluids that surround them. If a city is blanketed in smog or its water supply is contaminated, its inhabitants will become ill. Similarly, if the body fluid composition becomes abnormal, cells will be injured or destroyed. For example, suppose the temperature or salt content of the blood changes. The effect on the heart could range from the need for a minor adjustment (heart muscle tissue contracts more often, raising the heart rate) to a total disaster (the heart stops beating, so the individual dies).

Checkpoint

9. Identify the major levels of organization of the human body from the simplest to the most complex.
10. Identify the organ systems of the body and cite some major structures of each.
11. At which level of organization does a histologist investigate structures?

See the blue Answers tab at the back of the book.

1-4 Medical terminology is important to understanding anatomy and physiology

Learning Outcome Describe the origins of anatomical and physiological terms and explain the significance of standardizing terms.

Early anatomists faced serious problems when trying to communicate. Saying that a bump is “on the back,” for example, does not give very precise information about its location. So, anatomists created illustrated maps of the human body and gave each structure a specific name. They used prominent anatomical structures as landmarks, measured distances in centimeters or inches, and discussed these subjects in specialized directional terms. Modern anatomists continue to build on these practices. In effect, anatomy uses a special language that you must learn almost at the start of your study.

That special language, called **medical terminology**, involves using word roots, prefixes, suffixes, and combining forms to build terms related to the body in health and disease. Many of the anatomical and physiological terms you encounter in this textbook are derived from Greek or Latin roots that originated more than 1500 years ago. In fact, the term *anatomy* is derived from Greek roots that mean “a cutting open”; the term *physiology* also comes from Greek. Learning the word parts used in medical terminology will greatly assist in your study of anatomy and physiology and in your preparation for any health-related career.

There are four basic building blocks—or word parts—of medical terms. *Word roots* are the basic, meaningful parts of a term that cannot be broken down into another term with another definition. *Prefixes* are word elements that are attached to the beginning of words to modify their meaning but cannot stand alone. *Suffixes* are similar to prefixes, except they are word elements or letters added to the end of a word or word part to form another term. *Combining forms* are independent words or word roots that are used in combination with words, prefixes, suffixes, or other combining forms to build a new term. As we introduce new terms, we provide notes on pronunciation and relevant word parts. In addition, lists of commonly used word roots, prefixes, suffixes, and combining forms are found at the back of the text.

To show how medical terms are built, consider the word *pathology* (puh-THOL-ō-jē). Breaking this word into its basic parts reveals its meaning. The prefix *path-* refers to disease (the Greek term for “disease” is *pathos*). The suffix *-ology* means “study of.” So, pathology is the study of disease.

Latin and Greek terms are not the only ones that have been imported into the anatomical vocabulary over the centuries, and this vocabulary continues to expand. Many anatomical structures and clinical conditions were first named after either

the discoverer or, in the case of diseases, the most famous victim. During the past 100 years, most of these commemorative names, or **eponyms** (EH-pō-nimz), have been replaced by more precise terms. Where appropriate, we give both the eponym and the more precise term, because in clinical medicine, both terms may be used.

To avoid the miscommunication that plagued early anatomists, it is important for scientists throughout the world to use the same name for each body structure. For this reason, we used three texts, *Terminologia Anatomica* (TA), *Terminologia Histologica* (TH), and *Terminologia Embryologica* (TE) as guides to standardize our terms. These works, developed by the Federative International Committee on Anatomical Terminology, provide a common reference for terms by citing both Latin and English names. For example, the *tendo calcaneus* (Latin) is also called the calcaneal tendon (English). You may know the structure better by its eponym, the Achilles tendon.

1-5 Anatomical terms describe body regions, anatomical positions and directions, and body sections

Learning Outcome Use anatomical terms to describe body regions, body sections, and relative positions.

Anatomists use anatomical terms to describe body regions, relative positions and directions, and body sections, as well as major body cavities and their subdivisions. In the following sections we introduce the terms used in surface anatomy and sectional anatomy.

Surface Anatomy

Surface anatomy involves locating structures on or near the body surface. A familiarity with anatomical landmarks (structures that can be felt or palpated), anatomical regions (specific areas used for reference purposes), and terms for anatomical directions will make the material in subsequent chapters easier to understand.

Anatomical Landmarks

Understanding the terms and their origins helps you remember both the location of a particular structure and its name.

THE ORGAN SYSTEMS

Integumentary	Skeletal	Muscular	Nervous	Endocrine	Cardiovascular
 Major Organs • Skin • Hair • Sweat glands • Nails Functions • Protects against environmental hazards • Helps regulate body temperature • Provides sensory information	 Major Organs • Bones • Cartilages • Associated ligaments • Bone marrow Functions • Provides support and protection for other tissues • Stores calcium and other minerals • Forms blood cells	 Major Organs • Skeletal muscles and associated tendons Functions • Provides movement • Provides protection and support for other tissues • Generates heat that maintains body temperature	 Major Organs • Brain • Spinal cord • Peripheral nerves • Sense organs Functions • Directs immediate responses to stimuli • Coordinates or moderates activities of other organ systems • Provides and interprets sensory information about external conditions	 Major Organs • Pituitary gland • Thyroid gland • Pancreas • Adrenal glands • Gonads • Endocrine tissues in other systems Functions • Directs long-term changes in the activities of other organ systems • Adjusts metabolic activity and energy use by the body • Controls many structural and functional changes during development	 Major Organs • Heart • Blood • Blood vessels Functions • Distributes blood cells, water, and dissolved materials including nutrients, waste products, oxygen, and carbon dioxide • Distributes heat and assists in control of body temperature

Lymphatic	Respiratory	Digestive	Urinary	Male Reproductive	Female Reproductive
Major Organs • Spleen • Thymus • Lymphatic vessels • Lymph nodes • Tonsils Functions • Defends against infection and disease • Returns tissue fluids to the bloodstream	Major Organs • Nasal cavities • Sinuses • Larynx • Trachea • Bronchi • Lungs • Alveoli Functions • Delivers air to alveoli (sites in lungs where gas exchange occurs) • Provides oxygen to bloodstream • Removes carbon dioxide from bloodstream • Produces sounds for communication	Major Organs • Teeth • Tongue • Pharynx • Esophagus • Stomach • Small intestine • Large intestine • Liver • Gallbladder • Pancreas Functions • Processes and digests food • Absorbs and conserves water • Absorbs nutrients • Stores energy	Major Organs • Kidneys • Ureters • Urinary bladder • Urethra Functions • Excretes waste products from the blood • Controls water balance by regulating volume of urine produced • Stores urine prior to voluntary elimination • Regulates blood ion concentrations and pH	Major Organs • Testes • Epididymides • Ductus deferentia • Seminal vesicles • Prostate • Penis • Scrotum Functions • Produces sex cells (sperm), seminal fluids, and hormones • Sexual intercourse	Major Organs • Ovaries • Uterine tubes • Uterus • Vagina • Labia • Clitoris • Mammary glands Functions • Produces sex cells (oocytes) and hormones • Supports developing embryo from fertilization to delivery • Provides milk to nourish newborn infant • Sexual intercourse

Figure 1–3 Anatomical Landmarks. Anatomical terms are shown in boldface type and common names are in plain type.

Are the following anatomical landmarks visible from the anterior or posterior view: dorsal, gluteal, calcaneal?

For example, *brachial* refers to the arm, and later we consider the *brachialis muscle* and the *brachial artery*, which are in the arm, as their names suggest. **Figure 1–3** presents important anatomical landmarks.

The standard anatomical reference for the human form is the **anatomical position**. This is also called the *anatomic*

position. When the body is in this position, the hands are at the sides with the palms facing forward, and the feet are together. **Figure 1–3a** shows an individual in the anatomical position as seen from the front, called an *anterior view*. **Figure 1–3b** shows the body as seen from the back, called a *posterior view*. Unless otherwise noted, all descriptions in this

text refer to the body in the anatomical position. A person lying down is said to be **supine** (sū-PĪN) when face up and **prone** when face down.

Tips

Supine means “up.” To carry a bowl of *soup*, the hand must be in the *supine* position.

Anatomical Regions

To describe a general area of interest or injury, clinicians and anatomists often need broader terms in addition to specific landmarks. They use two methods—dividing into quadrants and dividing into regions—to map the surface of the abdomen and pelvis.

Clinicians refer to four **abdominopelvic quadrants** (Figure 1-4a) formed by a pair of imaginary perpendicular lines that intersect at the umbilicus (navel). This simple method of dividing into quadrants provides useful references for describing the location of aches, pains, and injuries. Knowing the location can help the clinician determine the possible cause. For example, tenderness in the right lower quadrant (RLQ) is a symptom of appendicitis. Tenderness in the right upper quadrant (RUQ), however, may indicate gallbladder or liver problems.

Anatomists prefer more precise terms to describe the location and orientation of internal organs. They recognize nine **abdominopelvic regions** (Figure 1-4b). Figure 1-4c shows the relationships among quadrants, regions, and internal organs.

Tips

The imaginary lines dividing the abdominopelvic regions resemble a tic-tac-toe game.

Anatomical Directions

Figure 1-5 introduces the main directional terms and gives some examples of their use. There are many different terms, and some can be used interchangeably. For example, *anterior* refers to the front of the body when viewed in the anatomical position. This term is equivalent to *ventral*, which refers to the belly. *Posterior* refers to the back of the body; this term is equivalent to *dorsal*. When reading anatomical descriptions, remember that the terms *left* and *right* always refer to the left and right sides of the *subject*, not of the observer.

Before you read further, analyze the image in detail, and practice using the terms. We start using these terms in the rest of this chapter. If you are familiar with the basic vocabulary, the anatomical descriptions throughout this textbook will be easier to follow.

Figure 1-4 Abdominopelvic Quadrants and Regions.

a Abdominopelvic quadrants. The four abdominopelvic quadrants are formed by two perpendicular lines that intersect at the navel (umbilicus). The terms for these quadrants, or their abbreviations, are most often used in clinical discussions.

b Abdominopelvic regions. The nine abdominopelvic regions provide more precise regional descriptions.

c Anatomical relationships. The relationship between the abdominopelvic quadrants and regions and the locations of the internal organs are shown here.

In which abdominopelvic quadrant and region is the stomach predominantly found?

Figure 1–5 Directional References.

Using directional references for a person in the anatomical position, describe the relationship of the hand compared to the elbow? Compared to the groin?

+ Clinical Note The Sounds of the Body

We pay attention to the sounds of the body because they provide evidence of typical function. Midwives and doctors used to place their ears directly on the patient's body to listen. Then a piece of new-fangled technology, called the *stethoscope*, was invented in 1816 that gave the patient more privacy and the practitioner a better listen. *Auscultation* (aws-kul-TA-shun) is the practice of listening to the various sounds made by body organs with a stethoscope. After a surgical operation, the recovery room nurse auscultates the patient's abdomen to listen for bowel sounds (called by the imitative term *borborygmi* [bor-bō-RIG-mī]). These sounds confirm that the intestine is resuming its characteristic motility after anesthesia. When students get their college physicals, the practitioner auscultates the lungs over the dorsal surface of the body and superior to the clavicles (where the tips of the lungs lie). It is often a thrilling moment when a pregnant female hears her baby's heartbeat for the first time with the help of an ultrasound technician. A Doppler ultrasound device bounces sound waves off a fetus's heart that are detected at the woman's skin surface in her pubic region (see Clinical Note: Diagnostic Imaging Techniques). The heartbeat is usually first heard when the fetus is about 12 weeks old. The sounds of an adult heart are heard at the general locations labeled on

the anterior thoracic region of the body shown here. The heart sounds of "lubb-dupp" (detailed in Chapter 20) indicate that heart valves are closing correctly during the heart's cycle. However, an unexpected "whoosh" can alert us to the possibility of a medical problem called a *heart murmur*.

1

Sectional Anatomy

Sometimes the only way to understand the relationships among the parts of a three-dimensional object is to slice through it and look at the internal organization. A slice through a three-dimensional object is called a *section*.

An understanding of sectional views is particularly important now that imaging techniques enable us to see inside the living body. These views are sometimes difficult to interpret, but it is worth spending the time required to understand what they show. Once you can interpret sectional views, you will have a good mental model for studying the anatomy and physiology of a particular region or system. Radiologists and other medical professionals responsible for interpreting medical scans spend much of their time analyzing sectional views of the body.

Any section through a three-dimensional object can be described in reference to a **sectional plane**, as indicated in **Figure 1–6**. A *plane* is a two-dimensional flat surface, and a *section* is a single view or slice along a plane. Common planes are frontal (coronal), sagittal, and transverse (horizontal).

- The **frontal (coronal) plane** is a vertical plane that divides the body or organ into anterior and posterior portions.

A cut in this plane is called a **frontal section**, or *coronal section*.

- The **sagittal plane** is a vertical plane that divides the body into left and right portions. A cut in this plane is called a **sagittal section**. If the plane lies in the middle, it is called a **midsagittal plane**, and if it is offset from the middle, it is called a **parasagittal plane**.
- The **transverse (horizontal) plane** divides the body into *superior* and *inferior* portions. A cut in this plane is called a **transverse section**, or *cross section*. Unless otherwise noted, in this textbook all anatomical diagrams that present cross-sectional views of the body are oriented as though the subject were supine with you, the observer, standing at the subject's feet and looking toward the head.

? Which plane separates the body into superior and inferior portions? Which plane separates the body into anterior and posterior portions?

1-6 Body cavities of the trunk protect internal organs and allow them to change shape

Learning Outcome Identify the major body cavities of the trunk and their subdivisions and describe the functions of each.

The body's trunk is subdivided into three major regions established by the body wall: the thoracic, abdominal, and pelvic regions. Most of our vital organs are located within these regions of the trunk. The true **body cavities** are closed, fluid filled, and lined by a thin tissue layer called a *serous membrane*, or *serosa*. The vital organs of the trunk are suspended within these body cavities; they do not simply lie there. Early anatomists used the term *cavity* when referring to internal regions. For example, everything deep to the chest wall of the thoracic region is within the **thoracic cavity**, and structures deep to the

abdominal and pelvic walls are said to lie within the **abdominopelvic cavity**. Internally, the **diaphragm** (DĪ-uh-fram), a flat muscular sheet, separates these anatomical regions.

The boundaries of the true body cavities and the regional "cavities" are not identical. For example, the thoracic cavity contains two *pleural cavities* (each surrounding a lung), the *pericardial cavity* (surrounding the heart), and the *mediastinum* (a large tissue mass). The *peritoneal cavity* (surrounding abdominal organs) extends only partway into the pelvic cavity (surrounding pelvic organs). **Figure 1–7** shows the boundaries between the subdivisions of the thoracic cavity and the abdominopelvic cavity.

The body cavities of the trunk have two essential functions: (1) They protect delicate organs from shocks and impacts, and (2) they permit significant changes in the size and shape of internal organs. For example, the lungs, heart, stomach, intestines,

Figure 1–7 Relationships among the Subdivisions of the Body Cavities of the Trunk.

urinary bladder, and many other organs can expand and contract without distorting surrounding tissues or disrupting the activities of nearby organs because they project into body cavities.

The internal organs that are enclosed by these cavities are known as **viscera** (VIS-e-ruh). A delicate serous membrane lines the walls of these internal cavities and covers the surfaces of the enclosed viscera. A watery fluid, called *serous fluid*, moistens serous membranes, coats opposing surfaces, and reduces friction. The portion of a serous membrane that directly covers a visceral organ is called the *visceral serosa*. The opposing layer that lines the inner surface of the body wall or chamber is called the *parietal serosa*. The parietal and visceral membranes are one membrane: The parietal serosa folds back onto itself, forming

the visceral serosa. Because the moist parietal and visceral serosae are usually in close contact, the body cavities are called *potential spaces*. In some clinical conditions, however, excess fluid can accumulate within these potential spaces, increasing their volume and exerting pressure on the enclosed viscera.

The Thoracic Cavity

The thoracic cavity contains the lungs and heart; associated organs of the respiratory, cardiovascular, and lymphatic systems; the inferior portions of the esophagus; and the thymus (**Figure 1–7a,c**). The thoracic cavity is subdivided into the left and right **pleural cavities** (surrounding the lungs), separated by a mass of tissue called the **mediastinum** (mē-dē-a-STĪ-num).

During the past several decades, rapid progress has been made in discovering more accurate and more detailed ways to image the human body, both in health and in disease.

X-rays

X-rays are the oldest and still the most common method of imaging. X-rays are a form of high-energy radiation that can penetrate living tissues. An x-ray beam travels through the body before striking a photographic plate. Not all of the projected x-rays arrive at the film. The body absorbs or deflects some of those x-rays. The ability to stop the passage of x-rays is referred to as **radiopacity**. When taking an x-ray, these areas that are impenetrable by x-rays appear light or white on the exposed film and are said to be **radiopaque**. In the body, air has the lowest radiopacity. Fat, liver, blood, muscle, and bone are increasingly radiopaque. As a result, radiopaque tissues look white, and less radiopaque tissues are in shades of gray to black.

To use x-rays to visualize soft tissues, a very radiopaque substance must be introduced. To study the upper digestive tract, a radiopaque barium solution is ingested by the patient. The resulting x-ray shows the contours of the stomach and intestines.

An x-ray of the skull, taken from the left side

A **barium-contrast x-ray** of the upper digestive tract

Standard Scanning Techniques

More recently, a variety of **scanning techniques** dependent on computers have been developed to show the less radiopaque, soft tissues of the body in much greater detail.

Diagrammatic views showing the relative position and orientation of the CT scan below and the MRI to the right.

CT scan of the abdomen

CT (computed tomography) **scans** use computers to reconstruct sectional views. A single x-ray source rotates around the body, and the x-ray beam strikes a sensor monitored by the computer. The x-ray source completes one revolution around the body every few seconds. It then moves a short distance and repeats the process. The result is usually displayed as a sectional view in black and white, but it can be colorized for visual effect. CT scans show three-dimensional relationships and soft tissue structures more clearly than do standard x-rays.

- Note that when anatomical diagrams or scans present cross-sectional views, the sections are presented from an inferior perspective, as though the observer were standing at the feet of a person in the supine position and looking toward the head.

MRI scan of the abdomen

An **MRI** of the same region (in this case, the abdomen) can show soft tissue structure in even greater detail than a CT scan. Magnetic resonance imaging surrounds part or all of the body with a magnetic field 3000 times as strong as that of Earth. This field causes particles within atoms throughout the body to line up in a uniform direction. Energy from pulses of radio waves is absorbed and released by the different atoms. The released energy is used to create a detailed image of the soft tissue structure.

PET scan of the brain

Positron emission tomography (**PET**) is an imaging technique that assesses metabolic and physiological activity of a structure. A PET scan is an important tool in evaluating healthy and diseased brain function.

Ultrasound of the uterus

In **ultrasound** procedures, a small transmitter contacting the skin broadcasts a brief, narrow burst of high-frequency sound and then detects the echoes. The sound waves are reflected by internal structures, and a picture, or **echogram**, is assembled from the pattern of echoes. These images lack the clarity of other procedures, but no adverse effects have been reported, and fetal development can be monitored without a significant risk of birth defects. Special methods of transmission and processing permit analysis of the beating heart without the complications that can accompany dye injections.

Special Scanning Methods

Spiral scan of the heart

A **spiral CT scan** is a form of three-dimensional imaging technology that is becoming increasingly important in clinical settings. During a spiral CT scan, the patient is on a platform that advances at a steady pace through the scanner while the imaging source, usually x-rays, rotates continuously around the patient. Because the x-ray detector gathers data quickly and continuously, a higher quality image is generated, and the patient is exposed to less radiation as compared to a standard CT scanner, which collects data more slowly and scans only one slice of the body at a time.

Digital subtraction angiography of coronary arteries

Digital subtraction angiography (DSA) is used to monitor blood flow through specific organs, such as the brain, heart, lungs, and kidneys. X-rays are taken before and after radiopaque dye is administered, and a computer “subtracts” details common to both images. The result is a high-contrast image showing the distribution of the dye.

Each pleural cavity surrounds a lung and is lined by a slippery serous membrane that reduces friction as the lung expands and recoils during breathing. The serous membrane lining a pleural cavity is called a *pleura* (PLOOR-ah). The *visceral pleura* covers the outer surfaces of a lung, and the *parietal pleura* covers the mediastinal surface and the inner body wall.

1 The mediastinum consists of a mass of connective tissue that surrounds, stabilizes, and supports the esophagus, trachea, and thymus, as well as the major blood vessels that originate or end at the heart. The mediastinum also contains the **pericardial cavity**, a small chamber that surrounds the heart. The relationship between the heart and the pericardial cavity resembles that of a fist pushing into a balloon (Figure 1-7b). The wrist corresponds to the *base* (attached portion) of the heart, and the balloon corresponds to the serous membrane that lines the pericardial cavity. The serous membrane associated with the heart is called the *pericardium* (*peri-*, around + *cardium*, heart). The layer covering the heart is the *visceral layer of serous pericardium*, and the opposing surface is the *parietal layer of serous pericardium*. During each beat, the heart changes in size and shape. The pericardial cavity permits these changes, and the slippery pericardial serous membrane lining prevents friction between the heart and nearby structures in the thoracic cavity.

The Abdominopelvic Cavity

The abdominopelvic cavity extends from the diaphragm to the pelvis. It is subdivided into a superior *abdominal cavity* and an inferior *pelvic cavity* (Figure 1-7a). The abdominopelvic cavity contains the **peritoneal** (per-i-tō-NĒ-al) **cavity**, a potential space lined by a serous membrane known as the *peritoneum* (per-i-tō-NĒ-um). The *parietal peritoneum* lines the inner surface of the body wall. A narrow space containing a small amount of fluid separates the parietal peritoneum from the *visceral peritoneum*, which covers the enclosed organs. You are probably already aware of the movements of the organs in this cavity. Most of us have had at least one embarrassing moment when a digestive organ contracted, producing a movement of liquid or gas and a gurgling or rumbling sound. The peritoneum allows the organs of the digestive system to slide across one another without damage to themselves or the walls of the cavity.

The **abdominal cavity** extends from the inferior (toward the feet) surface of the diaphragm to the level of the superior (toward the head) margins of the pelvis. This cavity contains the liver, stomach, spleen, small intestine, and most of the large intestine. (Look back at Figure 1-4c, which shows the positions of most of these organs.) The organs are partially or completely enclosed by the peritoneal cavity, much as the heart and lungs are enclosed by the pericardial and pleural cavities, respectively. A few organs, such as the kidneys and pancreas, lie between the peritoneal lining and the muscular wall of the abdominal cavity. Those organs are said to be *retroperitoneal* (*retro*, behind).

The **pelvic cavity** is inferior to the abdominal cavity. The bones of the pelvis form the walls of the pelvic cavity, and a layer of muscle forms its floor. The pelvic cavity contains the urinary bladder, various reproductive organs, and the distal (farthest) portion of the large intestine. In females, the pelvic cavity contains the ovaries, uterine tubes, and uterus. In males, it contains the prostate and seminal glands (seminal vesicles). The pelvic cavity also contains the inferior portion of the peritoneal cavity. The peritoneum covers the ovaries and the uterus in females, as well as the superior portion of the urinary bladder in both sexes. Organs such as the urinary bladder and the distal portions of the ureters and large intestine, which extend inferior to the peritoneal cavity, are said to be *infraperitoneal*.

The true body cavities of the trunk in the adult share a common embryological origin. The term “dorsal body cavity” is sometimes used to refer to the internal chamber of the skull (cranial cavity) and the space enclosed by the vertebrae (vertebral cavity). These chambers, which are defined by bony structures, are anatomically and embryonically distinct from true body cavities, and the term “dorsal body cavity” is not encountered in either clinical anatomy or comparative anatomy. For these reasons, we have avoided using that term in our discussion of body cavities.

A partial list of chambers, or spaces, within the body that are not true body cavities includes the cranial cavity, vertebral cavity, oral cavity, digestive cavity, orbits (eye sockets), tympanic cavity of each middle ear, nasal cavities, and paranasal sinuses (air-filled chambers within some cranial bones that are connected to the nasal cavities). These structures are discussed in later chapters.

The Clinical Note: Diagnostic Imaging Techniques highlights some clinical tests commonly used for viewing the interior of the body.

1-7 Physiological processes continuously regulate homeostasis

Learning Outcome Explain homeostasis.

Homeostasis (hō-mē-o-STĀ-sis; from the Greek *homeo*, similar + *stasis*, state of standing) refers to the continuous physiological processes that establish a relatively stable internal environment. Various physiological processes act to prevent harmful changes in the composition of body fluids and the environment inside our cells. Maintaining homeostasis is vital to an organism's survival. Failure to maintain homeostasis soon leads to illness or even death. The principle of homeostasis is the central theme of this text and the foundation of all modern physiology.

Mechanisms of Homeostatic Regulation

Homeostatic regulation is the adjustment of physiological systems to preserve homeostasis. Physiological systems have evolved to maintain homeostasis in an environment that is often inconsistent, unpredictable, and potentially dangerous. An understanding of homeostatic regulation is crucial to making accurate predictions about the body's responses to both normal and abnormal conditions.

Homeostatic regulation involves two general mechanisms: autoregulation and extrinsic regulation.

1. **Autoregulation** is a process that occurs when a cell, tissue, organ, or organ system adjusts in response to some environmental change. For example, when the oxygen level decreases in a tissue, the cells release chemicals that widen, or dilate, blood vessels. This dilation increases the blood flow and provides more oxygen to the region.
2. **Extrinsic regulation** is a process that results from the activities of the nervous system or endocrine system. These organ systems detect an environmental change and send an electrical signal (nervous system) or chemical messenger (endocrine system) to control or adjust the activities of another or many other systems simultaneously. For example, during exercise, the nervous system issues commands that increase heart rate so that blood circulates faster. The nervous system also causes blood flow to be reduced to less active organs, such as the digestive tract. The oxygen in circulating blood is then available to the active muscles, which need it most.

In general, the nervous system directs rapid, short-term, and very specific responses. For example, if a person accidentally sets their hand on a hot stove, the heat would produce a painful, localized disturbance of homeostasis. Your nervous system would respond by ordering specific muscles to contract and pull the hand away from the stove. These contractions last only if the neural activity continues, which is usually just a few seconds.

In contrast, the endocrine system releases chemical messengers called *hormones* into the bloodstream. These molecular messengers can affect tissues and organs throughout the body. The responses may not be immediately apparent, but they may persist for days or weeks. Examples of homeostatic regulation dependent on endocrine function include the long-term regulation of blood volume and composition and the adjustment of organ system function during starvation.

An Overview of Homeostatic Regulation

Regardless of the system involved, homeostatic regulation always works to keep the internal environment within certain limits, or a range. A homeostatic regulatory mechanism consists of three parts: (1) a **receptor**, a sensor that is sensitive to a particular stimulus or environmental change; (2) a

control center, which receives and processes the information supplied by the receptor and sends out commands; and (3) an **effector**, a cell or organ that responds to the commands of the control center and whose activity either opposes or enhances the stimulus. You are probably already familiar with similar mechanical regulatory mechanisms, such as the one involving the thermostat in a house or apartment (**Figure 1-8a**).

The thermostat is the control center. It receives information about room temperature from an internal or remote thermometer (a receptor). The setting on the thermostat establishes the **set point**, or desired value range, which in this case is the selected temperature. (In our example, the set point approximates 22°C, or about 72°F.) The function of the thermostat is to keep room temperature within acceptable limits, usually within a degree or so of the set point. In summer, the thermostat performs this function by controlling an air conditioner (an effector). When the temperature at the thermometer rises above the set point, the thermostat turns on the air conditioner, which then cools the room. Then, when the temperature at the thermometer returns to the set point, the thermostat turns off the air conditioner. The control is not precise, especially if the room is large and the thermostat is located on just one wall. Over time, the temperature in the center of the room fluctuates in a range above and below the set point (**Figure 1-8b**).

We can summarize the essential feature of temperature control by a thermostat very simply: A variation outside the set point triggers an automatic response that corrects the situation. In this way, variation in temperature is kept within an acceptable range. Now let's explore how the body uses a similar method of regulation called negative feedback.

21. Why is homeostatic regulation important to an organism?

See the blue Answers tab at the back of the book.

1-8 Negative feedback opposes variations from normal, whereas positive feedback enhances them

Learning Outcome Describe how negative feedback and positive feedback are involved in homeostatic regulation.

To keep variation in key body systems within ranges that are compatible with our long-term survival, the body uses a method of homeostatic regulation called *negative feedback*. In this process, an effector activated by the control center opposes, or *negates*, the original stimulus. In this way, negative feedback

Figure 1-8 The Control of Room Temperature.

a In response to input from a receptor (a thermometer), a control center (a thermostat) triggers an effector response (either an air conditioner or a heater) that restores normal temperature. In this case, when room temperature rises above the set point, the thermostat turns on the air conditioner, and the temperature returns to normal.

tends to minimize change. The body also has another method of homeostatic regulation called *positive feedback*, which instead tends to enhance or *increase* the change that triggered it. However, most homeostatic regulatory mechanisms involve negative feedback. Let's examine the roles of negative and positive feedback in homeostasis before considering the roles of organ systems in regulating homeostasis.

The Role of Negative Feedback in Homeostasis

An important example of **negative feedback**, a way of counteracting a change, is the control of body temperature, a process called *thermoregulation*. In thermoregulation, the relationship between heat loss, which takes place mainly at the body surface, and heat production, which takes place in all active tissues, is altered.

In the homeostatic control of body temperature (**Figure 1-9a**), the thermoregulatory control center is in the *hypothalamus*, a region of the brain. This control center receives information from two sets of temperature receptors, one in the skin and the other within the hypothalamus. At the normal set

point, body temperature (as measured with an oral thermometer) is approximately 37°C (98.6°F).

If body temperature rises above 37.2°C, activity in the control center targets two effectors: (1) muscle tissue lining the walls of blood vessels supplying blood to the skin and (2) sweat glands. The muscle tissue relaxes so the blood vessels dilate (widen), increasing blood flow through vessels near the body surface, and the sweat glands increase sweat secretion. The skin then acts like a radiator by losing heat to the environment, and the evaporation of sweat speeds the process.

As body temperature returns to normal, temperature in the hypothalamus decreases, and the thermoregulatory center becomes less active. Blood flow to the skin and sweat gland activity then decrease to previous levels. Body temperature drops below the set point as the secreted sweat evaporates.

Negative feedback is the primary mechanism of homeostatic regulation, and it provides long-term control over the body's internal conditions and systems. Homeostatic mechanisms using negative feedback normally ignore minor variations. They maintain a normal *range* rather than a fixed value. In our example, body temperature fluctuates around the set-point temperature (**Figure 1-9b**). The regulatory process

Figure 1–9 Negative Feedback: Control of Body Temperature. In negative feedback, a stimulus produces a response that opposes or negates the original stimulus.

a Events in the regulation of body temperature, which are comparable to those shown in Figure 1–8. A control center in the brain (the hypothalamus) functions as a thermostat with a set point of 37°C. If body temperature exceeds 37.2°C, heat loss is increased through increased blood flow to the skin and increased sweating.

If a person's body temperature gets too high, the body responds by decreasing its temperature to restore homeostasis. What are the homeostatic responses to an increase in body temperature?

itself is dynamic. That is, it is constantly changing because the set point may vary with changing environments or differing activity levels. For example, during sleep, the thermoregulatory set point is lower. When working outside on a hot day (or when a fever is present), it is set higher. Body temperature can vary from moment to moment or from day to day for any individual, due to either (1) small fluctuations around the set point or (2) changes in the set point. Comparable variations take place in all other aspects of physiology.

The variability among individuals is even greater than that within an individual. Each of us has homeostatic set points determined by genetic factors, age, sex, general health, and environmental conditions. For this reason, it is impractical to define “normal” homeostatic conditions very precisely. By convention, physiological values are reported either as average values obtained by sampling many people or as a range that includes 95% or more of the sample population.

For example, in 95% of healthy adults, body temperature ranges between 36.7°C and 37.2°C (98.1°F and 98.9°F). The other 5% of healthy adults have resting body temperatures that are below 36.7°C or above 37.2°C. These temperatures are perfectly normal for them, and the variations have no clinical significance. Physicians must keep this variability in mind when they review lab reports, because unusual values—even those outside the “normal” range—may represent individual variation rather than disease.

The Role of Positive Feedback in Homeostasis

In **positive feedback**, an initial stimulus produces a response that amplifies or enhances the original change in conditions, rather than opposing it. Positive feedback is seldom encountered in daily life, simply because it tends to produce extreme responses. For example, suppose that the thermostat in **Figure 1-8a** was accidentally connected to a heater rather than to an air conditioner. Now when room temperature rises above the set point, the thermostat turns on the heater, causing a further rise in room temperature. Room temperature continues to increase until someone switches off the thermostat, turns off the heater, or intervenes in some other way. This kind of escalating cycle is often called a **positive feedback loop**.

In the body, positive feedback loops are typically found when a potentially dangerous or stressful process must be completed quickly to restore homeostasis. For example, the immediate danger from a severe cut is the loss of blood, which can lower blood pressure and reduce the efficiency of the heart. The body's response to this blood loss is blood clotting, diagrammed in **Figure 1-10**. We examine blood clotting more closely in Chapter 19. Labor and delivery are other examples of positive feedback in action, as we discuss in Chapter 29.

The human body is amazingly effective at maintaining homeostasis. Nevertheless, an infection, injury, or genetic abnormality can sometimes have effects so severe that homeostatic

Figure 1-10 Positive Feedback: Blood Clotting. In positive feedback, a stimulus produces a response that accelerates or enhances the original change in conditions, rather than opposing it.

mechanisms cannot fully compensate for them. One or more variables within the internal environment may then be pushed outside their normal range of values. When this happens, organ systems begin to malfunction, producing a state known as illness, or **disease**. In Chapters 5–29, we devote much attention to the mechanisms that bring about many human diseases.

Systems Integration, Equilibrium, and Homeostasis

Homeostatic regulation controls aspects of the internal environment that affect every cell in the body. No single organ system has total control over any of these aspects. Instead, such control requires the coordinated efforts of multiple organ systems. In later chapters we explore the functions of each organ system and see how the systems interact to preserve homeostasis. **Table 1–1** lists the roles of various organ systems in regulating several important functions that are subject to homeostatic control. Note that in each case such regulation involves several organ systems.

A **state of equilibrium** exists when opposing processes or forces are in balance. In the case of body temperature, a state of equilibrium exists when the rate of heat loss equals the rate of heat production. Each physiological system functions to maintain a state of equilibrium that keeps vital conditions within a

normal range of values. This is often called a state of **dynamic equilibrium** because physiological systems are continually adapting and adjusting to changing conditions. For example, when muscles become more active, more heat is produced. More heat must then be lost at the skin surface to reestablish a state of equilibrium before body temperature rises outside normal ranges. Yet the adjustments made to control body temperature have other consequences. The sweating that increases heat loss at the skin surface increases losses of both water and salts. Other systems must then compensate for these losses and reestablish an equilibrium state for water and salts.

Note this general pattern: Any adjustments made by one physiological system have direct and indirect effects on a variety of other systems. Maintaining homeostasis is like a juggling act that keeps many different objects in the air.

Each organ system interacts with and depends on other organ systems, but introductory students may often find it easier to learn the basics of anatomy and physiology one system at a time. Chapters 5–29 are organized around individual systems, but remember that these systems all work together. The 11 *Build Your Knowledge Figures* in later chapters help reinforce this message. Each provides an overview of one system’s functions and summarizes its functional relationships with systems covered in previous chapters.

Table 1–1 The Roles of Organ Systems in Homeostatic Regulation

Internal Stimulus	Primary Organ Systems Involved	Functions of the Organ Systems
Body temperature	Integumentary system Muscular system Cardiovascular system Nervous system	Heat loss Heat production Heat distribution Coordination of blood flow, heat production, and heat loss
Body fluid composition		
Nutrient concentration	Digestive system Cardiovascular system Urinary system Skeletal system	Nutrient absorption, storage, and release Nutrient distribution Control of nutrient loss in the urine Mineral storage and release
Oxygen, carbon dioxide levels	Respiratory system Cardiovascular system	Absorption of oxygen, elimination of carbon dioxide Internal transport of oxygen and carbon dioxide
Levels of toxins and pathogens	Lymphatic system	Removal, destruction, or inactivation of toxins and pathogens
Body fluid volume	Urinary system Digestive system Integumentary system Cardiovascular system and lymphatic system	Elimination or conservation of water from the blood Absorption of water; loss of water in feces Loss of water through perspiration Distribution of water throughout body tissues
Waste concentration	Urinary system Digestive system Cardiovascular system	Excretion of wastes from the blood Elimination of wastes from the liver in feces Transport of wastes products to sites of excretion
Blood pressure	Cardiovascular system Nervous system and endocrine system	Pressure generated by the heart moves blood through blood vessels Adjustments in heart rate and blood vessel diameter can raise or lower blood pressure

✓ Checkpoint

22. Explain the function of negative feedback systems.
23. What happens to the body when homeostasis breaks down?
24. Explain how a positive feedback system works.
25. Why is positive feedback helpful in blood clotting but unsuitable for the regulation of body temperature?

26. Define equilibrium.
27. When the body continuously adapts by using homeostatic mechanisms, it is said to be in a state of _____ equilibrium.

See the blue Answers tab at the back of the book.

1 Chapter Review

Study Outline

An Introduction to Studying the Human Body

1. Biology is the study of life. One of its goals is to discover the unity and the patterns that underlie the diversity of organisms.

1-1 To make the most of your learning, read the text and view the art together

2. This text is divided into **sections**, which are units about a topic that continues to build on previously learned topics.
3. To enhance learning, the text and art should be read and studied together. For this reason, there is **text–art integration** whereby the figures are placed in proximity to the narrative.
4. **Learning outcomes** are tied to testing and indicate what educational goals should be achieved after reading each section. Learning outcomes identify the fundamental levels of learning from lower-order skills to higher-order skills. (Figure 1–1)

1-2 Anatomy (structure) and physiology (function) are closely integrated

5. **Anatomy** is the study of internal and external structures of the body and the physical relationships among body parts. **Physiology** is the study of how living organisms perform their vital functions.
6. Specific structures perform all physiological functions.
7. In **gross (macroscopic) anatomy**, we consider features that are visible without a microscope. This field includes *surface anatomy* (general form and superficial markings), *regional anatomy* (anatomical organization of specific areas of the body), *sectional anatomy* (relationship of the body's structures by examining cross sections of tissues or organs), and *systemic anatomy* (structure of organ systems). *Clinical anatomy* includes anatomical subspecialties important to the practice of medicine. In *developmental anatomy*, we examine the changes in form that occur between fertilization and physical maturity. In *embryology*, we study developmental processes that occur during the first 2 months of development.
8. The equipment used determines the limits of *microscopic anatomy*. In **cytology**, we analyze the internal structure of individual cells. In **histology**, we examine **tissues**, groups of cells that perform specific functions. Tissues combine to form **organs**, anatomical structures with multiple functions. (Spotlight Figure 1–2)
9. Human physiology is the study of the functions of the human body. It is based on *cell physiology*, the study of the functions of cells. In *organ physiology*, we study the physiology of specific

Media Resources:

- Interactive Physiology
- SmartArt Video
- A&P Flix
- PhysioEx

organs. In *systemic physiology*, we consider all aspects of the functioning of specific organ systems. In *pathological physiology*, we study the effects of diseases on organ or system functions.

1-3 Levels of organization progress from chemicals to a complete organism

10. Anatomical structures and physiological mechanisms occur in a series of interacting levels of organization. (Spotlight Figure 1–2)
11. The 11 **organ systems** of the body are the integumentary, skeletal, muscular, nervous, endocrine, cardiovascular, lymphatic, respiratory, digestive, urinary, and reproductive systems. (Spotlight Figure 1–2)

1-4 Medical terminology is important to understanding anatomy and physiology

12. **Medical terminology** is the use of word roots, prefixes, suffixes, and combining forms to construct anatomical, physiological, or medical terms.
13. *Terminologia Anatomica* (TA), *Terminologia Histologica* (TH), and *Terminologia Embryologica* (TE) were the references used to standardize terminology in this book.

1-5 Anatomical terms describe body regions, anatomical positions and directions, and body sections

14. The standard arrangement for anatomical reference is called the **anatomical position**. A person who is lying down is either **supine** (face up) or **prone** (face down). (Figure 1–3)
15. **Abdominopelvic quadrants** and **abdominopelvic regions** represent two approaches to describing anatomical regions of that portion of the body. (Figure 1–4)
16. The use of special directional terms provides clarity for the description of anatomical structures. (Figure 1–5)
17. The three **sectional planes** are **transverse** (*horizontal*), **frontal** (*coronal*), and **sagittal**. They describe relationships among the parts of the three-dimensional human body. (Figure 1–6)

1-6 Body cavities of the trunk protect internal organs and allow them to change shape

18. **Body cavities** protect delicate organs and permit significant changes in the size and shape of internal organs. The body cavities of the trunk surround organs of the respiratory, cardiovascular, digestive, urinary, and reproductive systems. (Figure 1-7)
19. The **diaphragm** divides the (superior) **thoracic** and (inferior) **abdominopelvic cavities**. The thoracic cavity consists of two **pleural cavities** (each surrounding a lung) with a central tissue mass known as the **mediastinum**. Within the mediastinum is the **pericardial cavity**, which surrounds the heart. The abdominopelvic cavity consists of the **abdominal cavity** and the **pelvic cavity** and contains the *peritoneal cavity*, a chamber lined by the *peritoneum*, a *serous membrane*. (Figure 1-7)
20. Diagnostic imaging techniques are used in clinical medicine to view the body's interior.

1-7 Physiological processes continuously regulate homeostasis

21. **Homeostasis** is the existence of a stable environment within the body.
22. Physiological systems preserve homeostasis through **homeostatic regulation**.
23. **Autoregulation** occurs when a cell, tissue, organ, or organ system adjusts its activities automatically in response to some environmental change. **Extrinsic regulation** results from the activities of the nervous system or endocrine system.
24. Homeostatic regulation mechanisms usually involve a **receptor** that is sensitive to a particular stimulus; a **control center**, which receives and processes the information supplied by the receptor and then sends out commands; and an **effector** that responds to the commands of the control center and whose activity either opposes or enhances the stimulus. (Figure 1-8)

1-8 Negative feedback opposes variations from normal, whereas positive feedback enhances them

25. **Negative feedback** is a corrective mechanism involving an action that directly opposes a variation from normal limits. (Figure 1-9)
26. In **positive feedback**, an initial stimulus produces a response that exaggerates or enhances the change in the original conditions, creating a **positive feedback loop**. (Figure 1-10)
27. No single organ system has total control over the body's internal environment; all organ systems work together. (Table 1-1)

Review Questions

See the blue Answers tab at the back of the book.

LEVEL 1 Reviewing Facts and Terms

1. Label the directional terms in the figures below.

- | | |
|-----------|-----------|
| (a) _____ | (b) _____ |
| (c) _____ | (d) _____ |
| (e) _____ | (f) _____ |
| (g) _____ | (h) _____ |
| (i) _____ | (j) _____ |

Match each numbered item with the most closely related lettered item. Use letters for answers in the spaces provided.

- | | |
|---|--|
| _____ 2. anatomy | (a) study of tissues |
| _____ 3. physiology | (b) constant internal environment |
| _____ 4. histology | (c) face-up position |
| _____ 5. mediastinum | (d) study of functions |
| _____ 6. homeostasis | (e) positive feedback |
| _____ 7. bone marrow | (f) organ system |
| _____ 8. liver | (g) thoracic tissue mass |
| _____ 9. skeletal | (h) negative feedback |
| _____ 10. temperature regulation | (i) serous membrane |
| _____ 11. labor and delivery | (j) study of internal and external body structures |
| _____ 12. supine | (k) diaphragm |
| _____ 13. prone | (l) place where blood cells are formed |
| _____ 14. divides thoracic and abdominopelvic body cavities | (m) surrounds lung |
| _____ 15. pleural cavity | (n) organ |
| _____ 16. pericardium | (o) face-down position |

17. The following is a list of six levels of organization that make up the human body.

- | | |
|--------------|------------------|
| (1) tissue | (2) cell |
| (3) organ | (4) chemical |
| (5) organism | (6) organ system |

The correct order, from the simplest to the most complex level, is

- (a) 2, 4, 1, 3, 6, 5, (b) 4, 2, 1, 3, 6, 5, (c) 4, 2, 1, 6, 3, 5, (d) 4, 2, 3, 1, 6, 5, (e) 2, 1, 4, 3, 5, 6.

54 UNIT 1 Levels of Organization

18. The study of the internal structure of individual cells is called (a) cell physiology, (b) cytology, (c) histology, (d) systemic anatomy.
19. The increasingly forceful labor contractions during childbirth are an example of (a) receptor activation, (b) effector shutdown, (c) negative feedback, (d) positive feedback.
20. A primary organ system involved in regulating body temperature is the (a) digestive system, (b) integumentary system, (c) lymphatic system, (d) urinary system.
21. A plane that runs parallel to the long axis of the body, dividing the body into equal right and left sides, is a (a) midsagittal section, (b) transverse section, (c) coronal section, (d) parasagittal section.
22. Which body cavity would enclose each of the following organs? (a) uterus, (b) prostate gland, (c) spleen, (d) lung.
23. The parietal pleura covers the (a) outer surfaces of a lung, (b) heart, (c) inner thoracic body wall, (d) enclosed abdominal organs.
24. A learning outcome is best described as (a) a goal of learning after reading a chapter section, (b) an abstract concept linking anatomy to physiology, (c) a type of homeostatic mechanism, (d) the same thing as text-art integration.

LEVEL 2 Reviewing Concepts

25. (a) Define anatomy.
(b) Define physiology.
26. The two major body cavities of the trunk are the (a) pleural cavity and pericardial cavity, (b) pericardial cavity and peritoneal cavity,

- (c) pleural cavity and peritoneal cavity, (d) thoracic cavity and abdominopelvic cavity.
27. What distinguishes autoregulation from extrinsic regulation?
28. Describe the anatomical position.
29. In which abdominopelvic region do you find (most of) the liver? (a) right hypochondriac region, (b) right lumbar region, (c) epigastric region, (d) umbilical region, (e) left hypochondriac region.
30. Which the following is *not* an example of negative feedback? (a) Increased pressure in the aorta triggers mechanisms to lower blood pressure. (b) A rise in blood calcium levels triggers the release of a hormone that lowers blood calcium levels. (c) A rise in estrogen during the menstrual cycle increases the number of progesterone receptors in the uterus. (d) Increased blood sugar stimulates the release of a hormone from the pancreas that stimulates the liver to store blood sugar.

LEVEL 3 Critical Thinking and Clinical Applications

31. The hormone *insulin* is released from the pancreas in response to an increased level of glucose (sugar) in the blood. If this hormone is controlled by negative feedback, what effect would insulin have on the blood glucose level?
32. A stroke occurs when blood flow to the brain is disrupted, causing brain cells to die. Why might a stroke result in a rise or fall of normal body temperature?

CLINICAL CASE Wrap-Up Using A&P to Save a Life

The patient is wheeled through the door and into Trauma Room 1. He is barely alive. Because of the location of the abdominal wound, in the right upper quadrant, and the likely depth of the wound, more than 6 inches, it is probable that the liver has been lacerated. Depending on the angle of the knife, sections of large intestine, containing bacteria that are deadly when released into the abdominal cavity, have probably also been lacerated. Any blood spilled onto the street or into the patient's abdominal cavity is lost from the cardiovascular system and cannot carry oxygen to body tissues. For this reason, the trauma nurse is ready with blood for transfusion.

An x-ray shows free air in the abdominal cavity, a sure sign the large intestine is cut. It also shows a fluid level indicating free blood in the abdominal cavity. Both conditions need immediate surgical attention. The patient is taken directly to the operating room, where

a surgeon performs open abdominal surgery. The lacerations of the liver and large intestine are repaired and the bleeding is stopped. A diverting colostomy is performed, creating an opening from the large intestine through the abdominal wall in the right lower quadrant, proximal to the level of injury. This allows the injured large intestine to rest while healing. A life is saved because an EMT, trauma nurse, and surgeon know their anatomy and physiology.

- Besides the liver and most of the large intestine, what other major organs are in the abdominal cavity?
- If the deep knife wound had been superior to the diaphragm, what body cavity would the knife have entered, and what organs does it contain?

See the blue Answers tab at the back of the book.

Related Clinical Terms

acute: A disease of short duration but typically severe.

chemotherapy: The treatment of disease or mental disorder by the use of chemical substances, especially the treatment of cancer by cytotoxic and other drugs.

chronic: Illness persisting for a long time or constantly recurring. Often contrasted with *acute*.

epidemiology: The branch of science that deals with the incidence, distribution, and possible control of diseases and other factors relating to health.

etiology: The science and study of the cause of diseases.

idiopathic: Denoting any disease or condition of unknown cause.

morbidity: The state of being diseased or unhealthy, or the incidence of disease in a population.

pathophysiology: The functional changes that accompany injury, disease, or a particular syndrome.

syndrome: A condition characterized by a group of associated symptoms.

2

The Chemical Level of Organization

Learning Outcomes

These Learning Outcomes correspond by number to this chapter's sections and indicate what you should be able to do after completing the chapter.

- 2-1 ■ Describe an atom and how atomic structure affects interactions between atoms.
- 2-2 ■ Compare the ways in which atoms combine to form molecules and compounds.
- 2-3 ■ Distinguish among the major types of chemical reactions that are important to physiology.
- 2-4 ■ Describe the role of enzymes in metabolism.
- 2-5 ■ Distinguish between inorganic compounds and organic compounds.
- 2-6 ■ Explain how the chemical properties of water make life possible.
- 2-7 ■ Explain what pH is and discuss its importance.
- 2-8 ■ Describe the physiological roles of acids, bases, and salts and the role of buffers in body fluids.
- 2-9 ■ Describe monomers and polymers, and the importance of functional groups in organic compounds.
- 2-10 ■ Discuss the structures and functions of carbohydrates.
- 2-11 ■ Discuss the structures and functions of lipids.
- 2-12 ■ Discuss the structures and functions of proteins.
- 2-13 ■ Discuss the structures and functions of nucleic acids.
- 2-14 ■ Discuss the structures and functions of high-energy compounds.

CLINICAL CASE

What Is Wrong with My Baby?

Sean is Maureen's first baby. Maureen and her husband, Conner, had enjoyed an uncomplicated pregnancy and delivery. Maureen had felt healthy throughout the pregnancy, but something was wrong with her baby.

2

Sean is 1 month old, and not thriving. He seems to have a good appetite and breastfeeds as if he were starving; yet he has dropped 20% of his normal birth weight of 7 pounds, 8 ounces. He is down to only 6 pounds at his 1-month checkup,

and his skin looks “wrinkly.” His stools appear greasy and foamy. Maureen also notices that Sean's skin tastes salty.

Most alarmingly, he seems to be having some difficulty breathing. His breathing is wheezy. Maureen and Conner are both from big families, yet none of the babies has ever been sickly like this.

What is wrong with baby Sean? To find out, turn to the Clinical Case Wrap-Up at the end of the chapter.

An Introduction to the Chemical Level of Organization

In this chapter we examine the structure of *atoms*, the basic chemical building blocks. You will also learn how atoms can combine to form increasingly complex structures, and how those complex structures function in the human body.

2-1 Atoms are the basic particles of matter

Learning Outcome Describe an atom and how atomic structure affects interactions between atoms.

Our study of the human body begins at the chemical level of organization. **Chemistry** is the science that deals with the structure of **matter**, defined as anything that takes up space and has mass. **Mass**, the amount of material in matter, is a physical property that determines the weight of an object in Earth's gravitational field. For our purposes, the mass of an object is the same as its weight. However, the two are not always equivalent: Orbiting the Earth you would be weightless, but your mass would remain unchanged.

The smallest stable units of matter are called **atoms**. Air, elephants, oranges, oceans, rocks, and people are all composed of atoms in varying combinations. The unique characteristics of each object, living or nonliving, result from the kinds of atoms involved and the ways those atoms combine and interact.

Atoms are composed of **subatomic particles**. Many different subatomic particles exist, but only three—*protons*, *neutrons*, and *electrons*—are important for understanding the chemical properties of matter. Protons and neutrons are similar in size and mass, but **protons** (p^+) have a positive electrical charge. **Neutrons** (n or n^0) are electrically *neutral*, or uncharged. **Electrons** (e^-) are much lighter than protons—only 1/1836 as massive—and have a negative electrical charge.

For this reason, the mass of an atom is determined primarily by the number of protons and neutrons in the **nucleus**, the central region of an atom. The mass of a large object, such as your body, is the sum of the masses of all its component atoms.

Atomic Structure

Atoms normally contain equal numbers of protons and electrons. The number of protons in an atom is its **atomic number**. *Hydrogen* (represented as H) is the simplest atom, with an atomic number of 1. An atom of hydrogen contains 1 proton and 1 electron. Hydrogen's proton is in the center of the atom and forms the nucleus. Hydrogen atoms seldom contain neutrons, but when present, they are also located in the nucleus. All atoms other than hydrogen have both neutrons and protons in their nuclei.

Electrons travel around the nucleus at high speed, within a spherical space called the **electron cloud** (Figure 2-1). We illustrate atomic structure in the simplified form shown for hydrogen in Figure 2-2a. In this two-dimensional representation, the electrons occupy a circular **electron shell**. One reason an electron tends to remain in its electron shell is that the negatively charged electron is attracted to the positively charged proton. The attraction between opposite electrical charges is an example of an *electrical force*. Electrical forces are involved in many physiological processes.

The dimensions of the electron cloud determine the overall size of the atom. To get an idea of the scale involved, consider that if the nucleus were the size of a tennis ball, the electron cloud of a hydrogen atom would have a radius of 10 kilometers (km), or about 6 miles! In reality, atoms are so small that atomic measurements are reported in nanometers (NAN-ō-mē-terz; nm). A nanometer is one-billionth of a meter, or 10^{-9} meter (0.000000001 m). The largest atoms approach 0.5 nm in diameter.

Figure 2-1 Hydrogen Atom with Electron Cloud. This space-filling model of a hydrogen atom represents the three-dimensional electron cloud formed by the movement of a single electron orbiting the nucleus.

Elements and Isotopes

An **element** is a pure substance composed of atoms of only one kind. As a result, each element has uniform composition and properties. Each element includes all the atoms with the same number of protons and thus the same atomic number. Only 92 elements exist in nature. Scientists have created about two dozen additional elements through nuclear reactions under special conditions in laboratories.

Every element has a chemical symbol, an abbreviation recognized by scientists everywhere. Most of the symbols are easy to connect with their English names (O for oxygen, N for nitrogen, and C for carbon), but a few are abbreviations of their Latin names. For example, the symbol for sodium, Na, comes from the Latin word *natrium*.

Elements cannot be changed or broken down into simpler substances, whether by chemical processing, heating, or other ordinary physical means. For example, an atom of carbon always remains an atom of carbon, regardless of the chemical events in which it may take part.

Our bodies consist of many elements, and the 13 most abundant elements are listed in **Table 2-1**. Our bodies also contain atoms of another 14 elements—called *trace elements*—that are present in very small amounts.

The atoms of a single element all have the same number of protons, but they can differ in the number of neutrons in the nucleus. For example, most hydrogen nuclei consist of just a single proton, but 0.015% also contain 1 neutron, and a very small percentage contain 2 neutrons (**Figure 2-2**). Atoms of the same element whose nuclei contain different numbers of neutrons are called **isotopes**.

Different isotopes of an element have essentially identical chemical properties and are alike except in mass. The **mass number**—the total number of protons plus neutrons in the nucleus of an atom—is used to distinguish isotopes. For example, hydrogen has 3 isotopes, distinguished by their mass numbers (1, 2, or 3). Hydrogen-1, or ^1H , has 1 proton and 1 electron (**Figure 2-2a**). Hydrogen-2, or ^2H , also known as *deuterium*, has 1 proton, 1 electron, and 1 neutron (**Figure 2-2b**). Hydrogen-3, or ^3H , also known as *tritium*, has 1 proton, 1 electron, and 2 neutrons (**Figure 2-2c**).

The nuclei of some isotopes are unstable, or radioactive. That is, they spontaneously break down and give off *radiation* (energy in the form of moving subatomic particles or waves) in

Table 2-1 Main Elements in the Human Body

Element (% of total body weight)	Significance
Oxygen, O (65)	Component of water and other compounds; gaseous form is essential for respiration
Carbon, C (18.6)	Found in all organic molecules
Hydrogen, H (9.7)	Component of water and most other compounds in the body
Nitrogen, N (3.2)	Found in proteins, nucleic acids, and other organic compounds
Calcium, Ca (1.8)	Found in bones and teeth; important for membrane function, nerve impulses, muscle contraction, and blood clotting
Phosphorus, P (1.0)	Found in bones and teeth, nucleic acids, and high-energy compounds
Potassium, K (0.4)	Important for proper membrane function, nerve impulses, and muscle contraction
Sodium, Na (0.2)	Important for blood volume, membrane function, nerve impulses, and muscle contraction
Chlorine, Cl (0.2)	Important for blood volume, membrane function, and water absorption
Magnesium, Mg (0.06)	Cofactor for many enzymes
Sulfur, S (0.04)	Found in many proteins
Iron, Fe (0.007)	Essential for oxygen transport and energy capture
Iodine, I (0.0002)	Component of hormones of the thyroid gland
Trace elements: silicon (Si), fluorine (F), copper (Cu), manganese (Mn), zinc (Zn), selenium (Se), cobalt (Co), molybdenum (Mo), cadmium (Cd), chromium (Cr), tin (Sn), aluminum (Al), boron (B), and vanadium (V)	Some function as cofactors; the functions of many trace elements are poorly understood

Figure 2-2 The Structure of Hydrogen Atoms. The three forms of hydrogen atoms are shown using the two-dimensional electron-shell model, which indicates the spherical electron cloud surrounding the nucleus.

a A typical hydrogen nucleus contains 1 proton and no neutrons.

b A deuterium (^2H) nucleus contains 1 proton and 1 neutron.

c A tritium (^3H) nucleus contains 1 proton and 2 neutrons.

measurable amounts. Such isotopes are called **radioisotopes**. The breakdown process is called *radioactive decay*. The decay rate of a radioisotope is commonly expressed as its **half-life**: the time required for half of a given amount of the isotope to decay. Radioisotopes differ radically in how rapidly they decay; their half-lives range from fractions of a second to billions of years.

Weakly radioactive isotopes are sometimes used in diagnostic procedures to monitor the structure or function of internal organs. However, strongly radioactive isotopes are dangerous, because the radiation they give off can alter the number of electrons in an atom, break apart molecules, and destroy cells and tissues.

Atomic Weights

A typical oxygen atom has an atomic number of 8 and contains 8 protons and 8 neutrons. The mass number of this isotope is therefore 16. The mass numbers of other isotopes of oxygen depend on the number of neutrons present. Mass numbers are useful because they represent the number of subatomic particles in the nuclei of different atoms. However, they do not indicate the *actual* mass of the atoms. For example, they do not take into account the masses of the electrons or the slight difference between the mass of a proton and that of a neutron. The actual mass of an atom of a specific isotope is known as its *atomic mass*.

The unit used to express atomic mass is the *atomic mass unit* (amu), or *dalton*. By international agreement, 1 amu is equal to one-twelfth the mass of a carbon-12 atom. One atomic mass unit is very close to the mass of a single proton or neutron. Thus, the atomic mass of an atom of the most common isotope of hydrogen is very close to 1, and that of the most common isotope of oxygen is very close to 16.

The **atomic weight** of an element is an average of the different atomic masses and proportions of its different isotopes.

This results in the atomic weight of an element being very close to the mass number of the most common isotope of that element. For example, the mass number of the most common isotope of hydrogen is 1, but the atomic weight of hydrogen is closer to 1.01, primarily because some hydrogen atoms (0.02%) have a mass number of 2, and even fewer have a mass number of 3.

Atoms take part in chemical reactions in fixed numerical ratios. To form water, for example, exactly 2 atoms of hydrogen combine with 1 atom of oxygen. But individual atoms are far too small and too numerous to be counted, so to determine the number of atoms we use a unit called the *mole*. For any element, a **mole** (abbreviated *mol*) is a specific quantity with a weight in grams equal to that element's atomic weight.

The mole is useful because 1 mol of a given element always contains the same number of atoms as 1 mol of any other element (just as we use *dozen* to stand for 12 items). That number, called *Avogadro's number*, is 6.023×10^{23} , or about 600 billion trillion. Expressing relationships in moles rather than in grams makes it much easier to keep track of the relative numbers of atoms in chemical samples and processes. For example, if a report stated that a sample contains 0.5 mol of hydrogen atoms and 0.5 mol of oxygen atoms, you would know immediately that the 2 elements were present in equal numbers. That would not be so evident if the report stated that there were 0.505 g of hydrogen atoms and 8.00 g of oxygen atoms. Most chemical analyses and clinical laboratory tests report data in moles (mol), millimoles (mmol – $1/1000$ mol, or 10^{-3} mol), or micromoles (μmol – $1/1,000,000$ mol, or 10^{-6} mol).

Electrons and Energy Levels

Atoms are electrically neutral. In other words, every positively charged proton is balanced by a negatively charged electron. Thus, each increase in the atomic number has a

comparable increase in the number of electrons traveling around the nucleus.

Within the electron cloud, electrons occupy an orderly series of *energy levels*. The electrons in an energy level may travel in complex patterns around the nucleus, but for our purposes the patterns can be diagrammed as a series of concentric electron shells. The first electron shell is the one closest to the nucleus, and it corresponds to the lowest energy level of electrons. Note that the terms *electron shell* and *energy level* can generally be used interchangeably.

There are up to eight energy levels in atoms, depending on their atomic number, but let's just look at the first three here. Each energy level is limited in the number of electrons it can hold. The first energy level can hold at most 2 electrons. The next two levels can each hold up to 8 electrons, an observation called the *octet rule*. Note that the maximum number of electrons that may occupy shells one through three corresponds to the number of elements in rows 1 through 3 of the periodic table of the elements (see Appendix E). The electrons in an atom occupy successive shells in an orderly manner: The first energy level fills before any electrons enter the second, and the second energy level fills before any electrons enter the third.

The outermost energy level, or electron shell, forms the "surface" of the atom and is called the **valence shell**. The *valence* of an element refers to its combining power with other atoms. The number of electrons in this level determines the chemical properties of the element. Atoms with unfilled valence shells are unstable—that is, they will react with other atoms, usually in ways that result in full valence shells. In contrast, atoms with a filled valence shell are stable and therefore do not readily react with other atoms.

As shown in **Figure 2-3a**, a hydrogen atom has 1 electron in the first energy level, the valence shell, so that level is unfilled. Therefore, a hydrogen atom readily reacts with other atoms. A helium atom has 2 electrons in its first energy level, which means its valence shell is filled (**Figure 2-3b**). This makes the helium atom very stable; it will not ordinarily react with other atoms. A lithium atom has 3 electrons (**Figure 2-3c**). Its first energy level can hold only 2 of them, so lithium has a single electron in a second, unfilled energy level. Thus, like hydrogen, lithium is unstable and reactive. The valence shell is filled in a neon atom, which has an atomic number of 10 (**Figure 2-3d**). Neon atoms, like helium atoms and other elements in the right-hand column of the periodic table, are very stable. The atoms of elements that are most important to biological systems are unstable (**Table 2-1**). Their instability promotes atomic interactions to form larger structures.

Figure 2-3 The Arrangement of Electrons into Energy Levels. The electron-shell model is also used to indicate the relative energy of electrons in an atom.

How many electrons can the second energy level hold when it is completely filled?

+ Clinical Note Radiation Sickness

Radiation sickness results from excessive exposure to ionizing radiation. It is characterized by fatigue, nausea, vomiting, and loss of teeth and hair. More severe cases cause anemia (low red blood cell count), central nervous damage, and death. In a clinical setting, it can occur when large doses of cancer-treating radiation are given to a person over a short time. X-rays and CT scans use low-dose radiation and do not cause radiation sickness. The amount of radiation received determines how sick a person can become. In 2011, a tsunami damaged a nuclear reactor in Fukushima, Japan, releasing a lethal radioactive form of iodine, I-131. Since then, public health officials have made potassium iodide (KI) available to people who live near such reactors. This benign salt saturates the thyroid gland with stable (nonradioactive) iodine so that it cannot absorb I-131.

✓ Checkpoint

1. Define atom.
2. Atoms of the same element that have different numbers of neutrons are called ____.
3. How is it possible for two samples of hydrogen to contain the same number of atoms, yet have different weights?

See the blue Answers tab at the back of the book.

2-2 Chemical bonds are forces formed by interactions between atoms

Learning Outcome Compare the ways in which atoms combine to form molecules and compounds.

Elements without active chemical properties are said to be *inert*. The noble gases helium, neon, and argon have filled valence shells and are called *inert gases*, because their atoms do not undergo chemical reactions.

Elements with unfilled valence shells, such as hydrogen and lithium, are called *reactive*, because they readily interact or combine with other atoms. Reactive atoms become stable by gaining, losing, or sharing electrons to fill their valence

shells. The interactions often involve the formation of **chemical bonds**, which hold the participating atoms together once the chemical reaction has ended.

When chemical bonding takes place, new chemical entities called *molecules* and *compounds* are created. Chemical bonding may or may not involve the sharing of electrons. The term **molecule** refers to any chemical structure consisting of atoms held together by shared electrons. A **compound** is a pure chemical substance made up of atoms of two or more different elements in a fixed proportion, regardless of whether electrons are shared or not. The two categories overlap, but they are not the same. Not all molecules are compounds, because some molecules consist of atoms of only one element. (For example, two oxygen atoms can be joined by sharing electrons to form a molecule of oxygen.) And not all compounds consist of molecules, because some compounds, such as ordinary table salt (sodium chloride) are held together by bonds that do not involve shared electrons.

Many substances, however, fit both categories. Take water, for example. Water is a compound because it contains two different elements—hydrogen and oxygen—in a fixed proportion of two hydrogen atoms to one oxygen atom. It also consists of molecules, because the two hydrogen atoms and one oxygen atom are held together by shared electrons. As described in later sections, most biologically important compounds, from carbohydrates to DNA, are molecules.

Regardless of the type of bonding involved, a chemical compound has properties that can be quite different from those of its components. For example, a mixture of hydrogen gas and oxygen gas can explode, but the explosion is a chemical reaction that produces liquid water, a compound used to put out fires.

The **molecular weight** of a molecule or compound is the sum of the atomic weights of its component atoms. It follows from the definition of the mole given previously that the molecular weight of a molecule or compound in grams is equal to the mass of 1 mol of molecules or a compound. Molecular weights are important because we cannot handle individual molecules or parts of a compound nor can we easily count the billions involved in chemical reactions in the body.

Let's use water, or H_2O , as an example of how to calculate a molecular weight. The atomic weight of hydrogen is 1.0079. To simplify our calculations, we round that value to 1. Then, 1 hydrogen molecule (H_2) with its 2 atoms has a molecular weight of 2 ($1 \times 2 = 2$). One oxygen atom has an atomic weight of 16. Summing up, the molecular weight of 1 molecule of H_2O is 18. One mole of water molecules would then have a mass of 18 grams.

The human body consists of countless molecules and compounds, so it is a challenge to describe these substances and their varied interactions. Chemists simplify such descriptions through a standardized system of *chemical notation*. The basic rules of this system for atoms and molecules are described in **Spotlight Figure 2-4a,b**.

In order to discuss the specific compounds that occur in the human body, we must be able to describe chemical compounds and reactions clearly. To do this, we use a simple form of “chemical shorthand” known as **chemical notation**. Chemical notation enables us to describe complex events briefly and precisely; its rules are summarized below.

a Atoms

The symbol of an element indicates 1 atom of that element. A number preceding the symbol of an element indicates more than 1 atom of that element.

VISUAL REPRESENTATION

CHEMICAL NOTATION

b Molecules

A numerical subscript following the symbol of an element indicates the number of atoms of that element in a molecule.

c Reactions

In a description of a chemical reaction, the participants at the start of the reaction are called reactants, and the reaction generates one or more products. Chemical reactions are represented by chemical equations. An arrow indicates the direction of the reaction, from reactants (usually on the left) to products (usually on the right). In the following reaction, 2 atoms of hydrogen combine with 1 atom of oxygen to produce a single molecule of water.

d Ions

A superscript plus or minus sign following the symbol of an element indicates an ion. A single plus sign indicates a cation with a charge of +1. (The original atom has given up 1 electron.) A single minus sign indicates an anion with a charge of -1. (The original atom has gained 1 electron.) If more than 1 electron is involved, the charge on the ion is indicated by a number preceding the plus or minus sign.

Write the chemical notation for each of these ions: sodium, chloride, and calcium.

In the sections that follow, we discuss three basic types of chemical bonds: *ionic bonds*, *covalent bonds*, and *hydrogen bonds*.

Ionic Bonds

An **ion** is an atom or group of atoms that has an electric charge, either positive or negative. Ions with a positive charge (+) are called **cations** (KAT- $\bar{\text{T}}$ -onz). Ions with a negative charge (–) are called **anions** (AN- $\bar{\text{T}}$ -onz).

Tips

Think of the **t** in **cation** as a plus sign (+) to remember that a **cation** has a positive charge; and think of the **n** in **anion** as standing for **negative** (–) to remember that **anions** have a negative charge.

Atoms become ions by losing or gaining electrons, so ions have an unequal number of protons and electrons. We assign a value of +1 to the charge on a proton, while the charge on an electron is –1. An atom that loses an electron becomes a cation with a charge of +1, because it then has 1 proton that lacks a corresponding electron. Losing a second electron would give the cation a charge of +2. Adding an extra electron to a neutral

atom produces an anion with a charge of –1. Adding a second electron gives the anion a charge of –2 (**Spotlight Figure 2–4d**).

Ionic bonds are chemical bonds created by the electrical attraction between anions and cations. In the formation of an ionic bond, the following steps occur:

1. One atom—the electron donor—loses one or more electrons and becomes a cation, with a positive (+) charge. Another atom—the electron acceptor—gains those same electrons and becomes an anion, with a negative (–) charge.
2. Attraction between the opposite charges then draws the two ions together.
3. An ionic compound is formed.

Figure 2–5a illustrates the formation of an ionic bond. The sodium atom diagrammed in **1** has an atomic number of 11, so this atom normally contains 11 protons and 11 electrons. (Because neutrons are electrically neutral, they do not affect the formation of ions or ionic bonds.) Electrons fill the first and second energy levels, and a single electron occupies the valence shell. Losing that 1 electron would give the sodium atom a full valence shell—the second energy level—and would produce a **sodium ion**, with a charge of +1. (The chemical shorthand for a sodium ion is Na^+ .) But a sodium atom cannot simply throw

Figure 2–5 Formation of Ionic Bonds.

- a Formation of an ionic bond.** **1** A sodium (Na) atom gives up an electron, which is gained by a chlorine (Cl) atom. **2** Because the sodium ion (Na^+) and chloride ion (Cl^-) have opposite charges, they are attracted to one another. **3** The association of sodium and chloride ions forms the ionic compound sodium chloride.

- b Sodium chloride crystal.** Large numbers of sodium and chloride ions form a crystal of sodium chloride (table salt).

- c Photo of sodium chloride crystals**

away the electron: The electron must be donated to an electron acceptor. A chlorine atom has 7 electrons in its valence shell, so it needs only 1 electron to achieve stability. A sodium atom can provide the extra electron. In the process (1), the chlorine atom becomes a **chloride ion** (Cl^-) with a charge of -1 .

Both atoms have now become stable ions with filled outermost energy levels. But the two ions do not move apart after the electron transfer, because the positively charged sodium ion is attracted to the negatively charged chloride ion (2). The combination of oppositely charged ions forms an **ionic compound**—in this case, **sodium chloride**, or NaCl (3). Large numbers of sodium and chloride ions interact to form highly structured crystals, held together by the strong electrical attraction of oppositely charged ions (Figure 2-5b,c).

Note that ionic compounds are not molecules. That is because they consist of a group of ions rather than atoms bonded by shared electrons. Sodium chloride and other ionic compounds are common in body fluids, but they are not present as intact crystals. When placed in water, many ionic compounds dissolve, and some or all the component anions and cations separate.

Covalent Bonds

Some atoms can complete their valence shells not by gaining or losing electrons, but by sharing electrons with other atoms. Such sharing creates **covalent** (kō-VĀ-lent) **bonds** between the atoms involved.

Individual hydrogen atoms, as diagrammed in Figure 2-2a, do not exist in nature. Instead, we find hydrogen molecules. Molecular hydrogen consists of a pair of hydrogen atoms (Figure 2-6). In chemical shorthand, molecular hydrogen is H_2 , where H is the chemical symbol for hydrogen, and the subscript 2 indicates the number of atoms. Molecular hydrogen is a gas that is present in the atmosphere in very small quantities. When the two hydrogen atoms share their electrons, each electron whirls around both nuclei. The sharing of one pair of electrons creates a **single covalent bond**, which can be represented by a single line ($-$) in the structural formula of a molecule.

Oxygen, with an atomic number of 8, has 2 electrons in its first energy level and 6 in its second. The oxygen atoms diagrammed in Figure 2-6 become stable by sharing two pairs of electrons, forming a **double covalent bond**, represented by two lines ($=$) in its structural formula. Molecular oxygen (O_2) is an atmospheric gas that most organisms need to survive. Our cells would die without a relatively constant supply of oxygen.

In our bodies, chemical processes that consume oxygen generally also produce **carbon dioxide** (CO_2) as a waste product. Each of the oxygen atoms in a carbon dioxide molecule forms double covalent bonds with the carbon atom, as Figure 2-6 shows.

Figure 2-6 Covalent Bonds in Five Common Molecules.

Molecule	Electron-Shell Model and Structural Formula	
Hydrogen (H_2)		$\text{H}-\text{H}$
Oxygen (O_2)		$\text{O}=\text{O}$
Carbon dioxide (CO_2)		$\text{O}=\text{C}=\text{O}$
Nitrogen (N_2)		$\text{N}\equiv\text{N}$
Nitric oxide (NO)		$\text{N}=\text{O}$

A triple covalent bond is the sharing of three pairs of electrons and is indicated by three lines ($\equiv$) in a structural formula. A triple covalent bond joins 2 nitrogen atoms to form molecular nitrogen (N_2) (Figure 2-6). Molecular nitrogen accounts for about 79% of our planet's atmosphere, but our cells ignore it completely. In fact, deep-sea divers live for long periods while breathing artificial air that does not contain nitrogen. (We discuss the reasons for eliminating nitrogen under these conditions in the Decompression Sickness Clinical Note in Chapter 23.)

Covalent bonds usually form molecules in which the valence shells of the atoms involved are filled. An atom, ion, or molecule that contains unpaired electrons in its valence shell is called a **free radical**. Free radicals are highly reactive. Almost as fast as it forms, a free radical enters additional reactions that are typically destructive. For example, free radicals can damage or destroy vital compounds, such as proteins. Evidence suggests that the cumulative damage from free radicals inside and outside our cells is a major factor in the aging process. Free radicals sometimes form during normal metabolism, but cells have several methods of removing or inactivating them.

Nitric oxide (NO), however, is a free radical with several important functions in the body (Figure 2-6). It reacts readily with other atoms or molecules, but it is involved in chemical communication in the nervous system, in the

control of blood vessel diameter, in blood clotting, and in the defense against bacteria and other pathogens (disease-causing organisms).

Tips

Remember this mnemonic for the covalent bonding of hydrogen, oxygen, nitrogen, and carbon atoms: HONC 1234.

Hydrogen shares 1 pair of electrons ($\text{H}-$), oxygen shares 2 pairs ($-\text{O}-$), nitrogen shares 3 pairs ($-\text{N}-$), and carbon shares 4 pairs ($-\text{C}-$).

Nonpolar Covalent Bonds

Covalent bonds are very strong, because the shared electrons hold the atoms together. In typical covalent bonds the atoms remain electrically neutral, because each shared electron spends just as much time “at home” as “away.” (If you and a friend were tossing a pair of baseballs back and forth as fast as you could, on average, each of you would have just one baseball.)

Many covalent bonds involve an equal sharing of electrons. Such bonds are called **nonpolar covalent bonds**. They occur, for instance, between 2 atoms of the same type. Nonpolar covalent bonds are very common. In fact, those involving carbon atoms form most of the structural components of the human body.

Polar Covalent Bonds

Covalent bonds involving different types of atoms may involve an unequal sharing of electrons, because the elements differ in how strongly they attract electrons. An unequal sharing of electrons creates a **polar covalent bond**. In chemistry, *polarity* refers to a separation of positive and negative electric charge. It can apply to a bond or entire molecule. For example, in a molecule of water, an oxygen atom forms covalent bonds with 2 hydrogen atoms (**Figure 2-7a**). The oxygen nucleus (with its 8 protons) has a much stronger attraction for the shared electrons than the hydrogen atoms (each with a single proton). As a result, the electrons spend more time orbiting the oxygen nucleus than orbiting the hydrogen nuclei.

Because the oxygen atom has 2 extra electrons most of the time, it develops a slight (partial) negative charge, indicated by δ^- , as shown in **Figure 2-7b**. At the same time, each hydrogen atom develops a slight (partial) positive charge, δ^+ , because its electron is away much of the time. (Suppose two friends were tossing a pair of baseballs back and forth, but one friend returned them as fast as possible while the other friend held onto them for a while before throwing them back. One friend would now, on average, have more than one baseball, and the other friend would have less than one.)

Figure 2-7 Water Molecules Contain Polar Covalent Bonds.

The unequal sharing of electrons makes polar covalent bonds somewhat weaker than nonpolar covalent bonds. Polar covalent bonds often create *polar molecules*—molecules that have positive and negative ends. Water is the most important polar molecule in the body.

Hydrogen Bonds

Covalent and ionic bonds tie atoms together to form molecules and/or compounds. Other, comparatively weak forces also act between adjacent molecules, and even between atoms within a large molecule. The most important of these weak attractive forces is the hydrogen bond. A **hydrogen bond** is the attraction between a slight positive charge (δ^+) on the hydrogen atom of a polar covalent bond and a slight negative charge (δ^-) on an oxygen, nitrogen, or fluorine atom of another polar covalent bond.

Hydrogen bonds are too weak to create molecules, but they can change the shapes of molecules or pull molecules closer together. For example, hydrogen bonding occurs between water molecules, forming clumps, or groups, of interconnected water molecules (**Figure 2-8**). At a water surface, this attraction between water molecules slows the evaporation rate and creates *surface tension*. Surface tension acts as a barrier that keeps lightweight objects that cannot break through the top layer of water molecules from entering the water. For example,

Figure 2-8 Hydrogen Bonds Form between Water Molecules. The hydrogen atoms of a water molecule have a slight positive charge, and the oxygen atom has a slight negative charge (see Figure 2-7b). The distances between these molecules have been exaggerated for clarity.

Hydrogen bonds do not form between two hydrogen atoms. Where do hydrogen bonds form?

it allows insects to walk across the surface of a pond or puddle. Similarly, the surface tension in a layer of tears on the eye prevents dust particles from touching the surface of the eye. At the cellular level, hydrogen bonds affect the shapes and properties of large, complex molecules, such as proteins and nucleic acids (including DNA).

States of Matter

Most matter in our environment exists in one of three states: solid, liquid, or gas. *Solids* have a constant volume and shape. A lump of granite, a brick, and a textbook are solid objects. *Liquids* have a constant volume, but no fixed shape. The shape of a liquid is determined by the shape of its container. Water, coffee, and tea are liquids. A *gas* has no constant volume and no fixed shape. Gases can be compressed or expanded, and unlike liquids they will fill a container of any size. The most familiar example is the air in our atmosphere.

What determines whether a substance is a solid, liquid, or gas? A matter's state depends on the degree of interaction among its atoms or molecules. The particles of a solid are held tightly together, while those of a gas are very far apart. Water is the only substance that occurs as a solid (ice), a liquid (water), and a gas (water vapor) at temperatures compatible with life. Water exists as a liquid over a broad range of temperatures

primarily because of hydrogen bonding among the water molecules. We talk more about water's unusual properties in Section 2-6.

Checkpoint

4. Define chemical bond and identify several types of chemical bonds.
5. Which kind of bond holds atoms in a water molecule together? What attracts water molecules to one another?
6. Both oxygen and neon are gases at room temperature. Oxygen combines readily with other elements, but neon does not. Why?

See the blue Answers tab at the back of the book.

2-3 Decomposition, synthesis, and exchange reactions are important types of chemical reactions in physiology

Learning Outcome Distinguish among the major types of chemical reactions that are important to physiology.

Cells stay alive and functional by controlling chemical reactions. In a **chemical reaction**, new chemical bonds form between atoms, or existing bonds between atoms are broken. These changes take place as atoms in the reacting substances, called **reactants**, are rearranged to form different substances, or **products** (**Spotlight Figure 2-4c**).

In effect, each cell is a chemical factory. Cells use chemical reactions to provide the energy they need to maintain homeostasis and to perform essential functions such as growth, maintenance and repair, secretion (discharging from a cell), and contraction. All the reactions under way in the cells and tissues of the body at any given moment make up its **metabolism** (me-TAB-ō-lizm).

Basic Energy Concepts

An understanding of some basic relationships between matter and energy is helpful for any discussion of chemical reactions. **Work** is the movement of an object or a change in the physical structure of matter. In the body, work includes movements such as walking or running, the synthesis of *organic* (carbon-containing) molecules, and the conversion of liquid water to water vapor (evaporation). **Energy** is the capacity to do work, and movement or physical change cannot take place without energy. The two major types of energy are kinetic energy and potential energy:

- **Kinetic energy** is the energy of motion—energy that can be transferred to another object and do work. When falling off a ladder, it is kinetic energy that does the damage.

- **Potential energy** is stored energy—energy that has the potential to do work. It may derive from an object's position (a person standing on a ladder) or from its physical or chemical structure (a stretched spring or a charged battery).

Kinetic energy must be used in climbing the ladder, in stretching the spring, or in charging the battery. The resulting potential energy is converted back into kinetic energy when the person descends, the spring recoils, or the battery discharges. The kinetic energy can then be used to perform work. For example, in an MP3 player, the chemical potential energy stored in small batteries is converted to kinetic energy that vibrates the sound-producing membranes in headphones or external speakers.

Energy cannot be destroyed: It can only be converted from one form to another. A conversion between potential energy and kinetic energy is never 100% efficient. Each time an energy exchange occurs, some of the energy is released in the form of heat. *Heat* is an increase in random molecular motion, and the temperature of an object is proportional to the average kinetic energy of its molecules. Heat can never be completely converted to work or any other form of energy, and cells cannot capture it or use it to do work.

Cells do work as they use energy to synthesize complex molecules and move materials into, out of, and within the cell. The cells of a skeletal muscle at rest, for example, contain potential energy in the form of the positions of protein filaments and the covalent bonds between molecules inside the cells. When a muscle contracts, it performs work. Potential energy is converted into kinetic energy, and heat is released. The amount of heat is proportional to the amount of work done. As a result, during exercise, body temperature rises.

Types of Chemical Reactions

Three types of chemical reactions are important to the study of physiology: decomposition reactions, synthesis reactions, and exchange reactions. Many of these chemical reactions are also *reversible reactions*.

Decomposition Reactions

A **decomposition reaction** breaks a molecule into smaller fragments. Here is a diagram of a simple *decomposition reaction*:

Decomposition reactions take place outside cells as well as inside them. For example, a typical meal contains molecules of fats, sugars, and proteins that are too large and too complex to be absorbed and used by the body. Decomposition reactions in the digestive tract break these molecules down into smaller fragments that can be absorbed.

Decomposition reactions involving water are important in the breakdown of complex molecules in the body. In this process, which is called a **hydrolysis reaction** (hī-DROL-i-sis;

hydro-, water + *lysis*, a loosening), one of the bonds in a complex molecule is broken, and the components of a water molecule (H and OH) are added to the resulting fragments:

Collectively, the decomposition reactions of complex molecules within the body's cells and tissues are referred to as **catabolism** (ka-TAB-ō-lizm; *katabole*, a throwing down). When a covalent bond—a form of potential energy—is broken, it releases kinetic energy that can do work. By harnessing the energy released in this way, cells carry out vital functions such as growth, movement, and reproduction.

Synthesis Reactions

Synthesis (SIN-the-sis) is the opposite of decomposition. A **synthesis reaction** assembles smaller molecules into larger molecules. A simple synthetic reaction is diagrammed here:

Synthesis reactions may involve individual atoms or the combination of molecules to form even larger products. The formation of water from hydrogen and oxygen molecules is a synthesis reaction. Synthesis always involves the formation of new chemical bonds, whether the reactants are atoms or molecules.

A **dehydration synthesis**, or *condensation, reaction* is the formation of a complex molecule by the removal of a water molecule:

Dehydration synthesis is the opposite of hydrolysis. We look at examples of both reactions in later sections (Sections 2-9, 2-10, and 2-11).

Collectively, the synthesis of new molecules within the body's cells and tissues is known as **anabolism** (a-NAB-ō-lizm; *anabole*, a throwing upward). Anabolism is usually considered an "uphill" process because it takes energy to create a chemical bond (just as it takes energy to push something uphill). Cells must balance their energy budgets, with catabolism providing the energy to support anabolism and other vital functions.

Tips

To remember the difference between anabolism (synthesis) and catabolism (breakdown), relate the terms to words you may already know: Anabolic steroids are used to build up muscle tissue, while both catastrophe and catabolism involve destruction (breakdown).

Exchange Reactions

In an **exchange reaction**, parts of the reacting molecules are shuffled around to produce new products:

The reactants and products contain the same components (A, B, C, and D), but those components are present in different combinations. In an exchange reaction, the reactant molecules AB and CD must break apart (a decomposition) before they can interact with each other to form AD and CB (a synthesis).

Reversible Reactions

At least in theory, chemical reactions are reversible, so if $A + B \longrightarrow AB$, then $AB \longrightarrow A + B$. Many important biological reactions are freely reversible. Such reactions can be represented as an equation:

This equation indicates that, in a sense, two reactions are taking place at the same time. One is a synthesis reaction ($A + B \rightarrow AB$) and the other is a decomposition reaction ($AB \rightarrow A + B$).

Recall from Chapter 1 that a state of *equilibrium* exists when opposing processes or forces are in balance. At equilibrium, the rates of the two reactions are in balance. As fast as one molecule of AB forms, another degrades into A + B.

What happens when equilibrium is disturbed—for example, if more AB is added? In our example, the rate of the synthesis reaction is directly proportional to the frequency of encounters between A and B. In turn, the frequency of encounters depends on the degree of crowding. (A person is much more likely to bump into another person in a crowded room than in a room that is almost empty.) So, adding more AB molecules will increase the rate of conversion of AB to A and B. The amounts of A and B will then increase, leading to an increase in the rate of the reverse reaction—the formation of AB from A and B. Eventually, a balance, or equilibrium, is again established.

Tips

Jell-O provides an example of a physical reversible reaction. Once Jell-O has been refrigerated, the gelatin sets up and forms a solid, but if it sits without refrigeration for too long, it turns back into a liquid again.

Checkpoint

- Using the rules for chemical notation, how is an ion's electrical charge represented?
- Using the rules for chemical notation, write the molecular formula for glucose, a compound composed of 6 carbon atoms, 12 hydrogen atoms, and 6 oxygen atoms.
- Identify and describe three types of chemical reactions important to human physiology.
- In cells, glucose, a six-carbon molecule, is converted into two three-carbon molecules by a reaction that releases energy. What type of reaction is this?

See the blue Answers tab at the back of the book.

2-4 Enzymes speed up reactions by lowering the energy needed to start them

Learning Outcome Describe the role of enzymes in metabolism.

Most **biochemical reactions** (those that happen in living organisms) do not take place spontaneously, or if they do, they occur so slowly that they would be of little value to living cells. Before a reaction can proceed, enough energy must be provided to activate the reactants. The amount of energy required to start a reaction is called the **activation energy**. Many reactions can be activated by changes in temperature or acidity, but such changes are deadly to cells. For example, every day cells break down complex sugars as part of normal metabolism. Yet to break down a complex sugar in a laboratory, it must be boiled in an acidic solution. Human body cells don't have that option! Temperatures that high and solutions that corrosive would immediately destroy living tissues. Instead, cells use special proteins called *enzymes* to catalyze (speed up) most of the complex synthesis and decomposition reactions in the body.

Enzymes promote chemical reactions by lowering their required activation energy (Figure 2-9). In doing so, they make it possible for chemical reactions, such as the breakdown of sugars, to take place under conditions compatible with life. Cells make enzyme molecules, each of which promotes a specific reaction.

Enzymes belong to a class of substances called **catalysts** (KAT-uh-lists; *katalysis*, dissolution), compounds that speed

Figure 2-9 Enzymes Lower Activation Energy. Enzymes lower the activation energy required for a chemical reaction to proceed readily (in order, from 1–4) under conditions in the body.

Which number represents the greatest amount of energy that must be overcome during the reaction? Which number represents the lowest amount of reaction energy?

up chemical reactions without themselves being permanently changed or consumed. Enzymatic reactions, which are reversible, can be written as

An appropriate enzyme can accelerate, or speed up, a reaction, but an enzyme affects only the *rate* of the reaction, not its direction or the products that are formed. An enzyme cannot bring about a reaction that would otherwise be impossible. Enzymatic reactions are generally reversible, and they proceed until equilibrium is reached.

The complex reactions that support life take place in a series of interlocking steps, each controlled by a specific enzyme. Such a reaction sequence is called a *metabolic pathway*. A synthetic pathway can be diagrammed as follows:

In many cases, the steps in the synthetic pathway differ from those in the decomposition pathway, and separate enzymes are often involved.

It takes activation energy to start a chemical reaction, but once it has begun, the reaction may absorb or release energy as it proceeds to completion. If the amount of energy released is greater than the activation energy needed to start the reaction, there will be a net release of energy. Reactions that release energy are said to be **exergonic** (*exo-*, outside + *ergon*, work). Exergonic reactions are relatively common in the body. They generate the heat that maintains body temperature.

If more energy is required to begin the reaction than is released as it proceeds, the reaction will absorb energy. Such reactions are called **endergonic** (*endo-*, inside). The synthesis of molecules such as fats and proteins results from endergonic reactions.

✓ Checkpoint

11. What is an enzyme?
12. Why are enzymes needed in our cells?

See the blue Answers tab at the back of the book.

2-5 Inorganic compounds lack carbon, and organic compounds contain carbon

Learning Outcome Distinguish between inorganic compounds and organic compounds.

The human body is very complex, but it contains relatively few elements. Just knowing the identity and quantity of each element in the body will not help you understand the body any more than memorizing the alphabet will help you understand this text. Just as 26 letters can be combined to form thousands of different words in this text, only about 26 elements combine to form thousands of different chemical compounds in our bodies. As we saw in Chapter 1, these compounds make up

the living cells that form the body's framework and carry on all its life processes. Learning about the major classes of chemical compounds helps you to understand the structure and function of the human body.

Two of the major classes of compounds are nutrients and metabolites. **Nutrients** are the substances from food that are necessary for normal physiological functions. Nutrients include carbohydrates, proteins, lipids (fats), vitamins, minerals, and water. **Metabolites** (me-TAB-ō-lītz; *metabole*, change) are substances that are involved in, or are a by-product of, metabolism. We can broadly categorize nutrients and metabolites as either inorganic or organic. **Inorganic compounds** generally do not contain carbon and hydrogen atoms as their primary structural components. (If present, they do not form C—H bonds.) In contrast, carbon and hydrogen always form the basis for **organic compounds**. Their molecules can be much larger and more complex than inorganic compounds. *Carbohydrates*, *proteins*, and *lipids* are organic nutrients used by the body—we cover these in later sections.

The most important inorganic compounds in the body are as follows:

- *carbon dioxide*, a byproduct of cell metabolism;
- *oxygen*, an atmospheric gas required in important metabolic reactions;
- *water*, which accounts for more than half of our body weight; and
- *acids*, *bases*, and *salts*—compounds held together partially or completely by ionic bonds.

In the next section, we focus on water, its properties, and how those properties establish the conditions necessary for life. Most of the other inorganic molecules and compounds in the body exist in association with water, the primary component of our body fluids. Both carbon dioxide and oxygen, for example, are gas molecules that are transported in body fluids. Also, all the inorganic acids, bases, and salts we discuss are dissolved in body fluids.

✓ Checkpoint

13. Compare inorganic compounds to organic compounds.

See the blue Answers tab at the back of the book.

2-6 Physiological systems depend on water

Learning Outcome Explain how the chemical properties of water make life possible.

Water (H₂O) is the most important substance in the body. It makes up to two-thirds of total body weight. A change in the body's water content can be fatal, because virtually all physiological systems will be affected.

Although water is familiar to everyone, it has some highly unusual properties: universal solvent, reactivity, high heat capacity, and lubrication. All are important to the human body.

- **Universal Solvent.** A remarkable number of inorganic and organic molecules and compounds are water-soluble, meaning they will dissolve or break up in water. The individual particles become distributed within the water, and the result is a **solution**—a uniform mixture of two or more substances. The liquid in which other atoms, ions, or molecules are distributed is called the **solvent**. The dissolved substances are the **solutes**. In *aqueous* (AK-wē-us) *solutions*, water is the solvent. Water is often called a “universal solvent” because more substances dissolve in it than any other liquid.
- **Reactivity.** In our bodies, chemical reactions take place in water, but water molecules are also reactants in some reactions. Hydrolysis and dehydration synthesis are two examples noted earlier in the chapter.
- **High Heat Capacity.** **Heat capacity** is the quantity of heat required to raise the temperature of a unit mass of a substance 1°C. Water has an unusually high heat capacity because water molecules in the liquid state are attracted to one another through hydrogen bonding. Important consequences of this attraction include the following:
 - The temperature of water must be quite high (it requires a lot of energy) to break all the hydrogen bonds between individual water molecules and allow them to escape and become water vapor, a gas. Therefore, water remains a liquid over a broad range of environmental temperatures, and the freezing and boiling points of water are far apart.
 - Water carries a great deal of heat away with it when it changes from a liquid to a gas. This feature explains the cooling effect of perspiration on the skin.
 - An unusually large amount of heat energy is required to change the temperature of 1 g of water by 1°C. As a result, a large mass of water changes temperature slowly. This property is called *thermal inertia*. Thermal inertia helps stabilize body temperature because water accounts for up to two-thirds of the weight of the human body.
- **Lubrication.** Water is an effective lubricant because there is little friction between water molecules. So even a thin layer of water between two opposing surfaces will greatly reduce friction between them. (That is why driving on wet roads can be hazardous. A car’s tires may start sliding on a layer of water rather than maintaining contact with the road.) Within joints such as the knee, an aqueous solution prevents friction between the opposing surfaces. Similarly, a small amount of fluid in the body cavities prevents friction between internal organs, such as the heart or lungs, and the body wall.

The Properties of Aqueous Solutions

Water’s chemical structure makes it an unusually effective solvent. The covalent bonds in a water molecule are oriented so that the hydrogen atoms are fairly close together. As a result, the water molecule has positive- and negative-charged ends, or poles (**Figure 2–10a**). For this reason, a water molecule is called a **polar molecule**.

Many inorganic compounds are held together partly or completely by ionic bonds. In water, these compounds undergo **dissociation** (di-sō-sē-Ā-shun)—the splitting of a compound into smaller molecules. **Ionization** (ī-on-i-ZĀ-shun) is the dissociation into ions. In this process, ionic bonds are broken as the individual ions interact with the positive or negative ends of polar water molecules (**Figure 2–10b**). The result is a mixture of cations and anions surrounded by water molecules. The water molecules around each ion form a *hydration sphere* that isolates the ions from each other, thus preventing the formation of ionic bonds.

An aqueous solution containing anions and cations will conduct an electrical current. When this happens, cations (+) move toward the negative side, and anions (–) move toward the positive side. Electrical forces across plasma membranes affect the functioning of all cells, and small electrical currents carried by ions are essential to muscle contraction and nerve function.

Electrolytes and Body Fluids

Soluble inorganic substances whose ions will conduct an electrical current in solution are called **electrolytes** (e-LEK-trō-lītz). Sodium chloride in solution is an electrolyte. The dissociation of electrolytes in blood and other body fluids releases a variety of ions. **Table 2–2** lists important electrolytes and the ions released when they dissociate.

Changes in the concentrations of electrolytes in body fluids will disturb almost every vital function. For example, a declining potassium ion (K^+) level will lead to a general muscular paralysis, and a rising concentration will cause weak and irregular heartbeats. The concentrations of ions in

Table 2–2 Important Electrolytes That Dissociate in Body Fluids

Electrolyte	Ions Released
NaCl (sodium chloride)	$\rightarrow Na^+ + Cl^-$
KCl (potassium chloride)	$\rightarrow K^+ + Cl^-$
CaPO₄ (calcium phosphate)	$\rightarrow Ca^{2+} + PO_4^{2-}$
NaHCO₃ (sodium bicarbonate)	$\rightarrow Na^+ + HCO_3^-$
MgCl₂ (magnesium chloride)	$\rightarrow Mg^{2+} + 2Cl^-$
Na₂HPO₄ (sodium hydrogen phosphate)	$\rightarrow 2Na^+ + HPO_4^{2-}$
Na₂SO₄ (sodium sulfate)	$\rightarrow 2Na^+ + SO_4^{2-}$

Figure 2–10 Water Molecules Surround Solutes in Aqueous Solutions.

body fluids are carefully regulated, mostly by the coordination of activities at the kidneys (ion excretion), the digestive tract (ion absorption), and the skeletal system (ion storage or release).

Hydrophilic and Hydrophobic Compounds

Some organic molecules contain polar covalent bonds, which also attract water molecules. The hydration spheres that form may then carry these molecules into solution. Molecules that interact readily with water molecules in this way are called **hydrophilic** (hī-drō-FIL-ik; *hydro-*, water + *philos*, loving). Glucose, an important soluble sugar, is one example (**Figure 2–10c**).

When nonpolar molecules are exposed to water, hydration spheres do not form and the molecules do not dissolve. Molecules that do not readily interact with water are called **hydrophobic** (hī-drō-FÖB-ik; *hydro-*, water + *phobos*, fear). Fats and oils of all kinds are some of the most familiar hydrophobic molecules. For example, body fat deposits consist of large, hydrophobic droplets trapped in the watery interior of cells. Gasoline and heating oil are hydrophobic molecules not found in the body. When accidentally spilled into lakes or oceans, they form long-lasting oil slicks instead of dissolving.

Tips

To distinguish between hydrophobic and hydrophilic, remember that a phobia is a fear of something, and that the suffix *-philic* ends with “lic,” which resembles “like.”

Colloids and Suspensions

Body fluids may contain large and complex organic molecules, such as proteins, that are held in solution by their association with water molecules (**Figure 2–10c**). A solution containing dispersed proteins or other large molecules is called a **colloid** (KOL-oyd). Liquid Jell-O is a familiar colloid. The particles or molecules in a colloid do not settle and will remain in solution indefinitely.

In contrast, a **suspension** contains large particles in solution, but if undisturbed, its particles will settle out of solution due to gravity. For example, stirring beach sand into a bucket of water creates a suspension that will last only until the sand settles to the bottom. Whole blood is another suspension because the blood cells are dispersed in the blood plasma. However, if clotting is prevented, the cells in a blood sample will gradually settle to the bottom of the container. Measuring that settling rate, or “sedimentation rate,” is a common laboratory test.

✓ Checkpoint

14. Explain how the chemical properties of water make life possible.

See the blue Answers tab at the back of the book.

2-7 Body fluid pH is vital for homeostasis

Learning Outcome Explain what pH is and discuss its importance.

A hydrogen atom involved in a chemical bond or participating in a chemical reaction can easily lose its electron to become a **hydrogen ion (H^+)**. Hydrogen ions are extremely reactive in solution. In excessive numbers, they will disrupt cell and tissue functions. As a result, the concentration of hydrogen ions in body fluids must be regulated precisely.

A few hydrogen ions are normally present even in a sample of pure water, because some of the water molecules dissociate spontaneously, releasing cations and anions. The dissociation of water is a reversible reaction. We can represent it as

Notice that the dissociation of one water molecule yields a hydrogen ion (H^+) and a **hydroxide** (hī-DROK-sīd) **ion (OH^-)**.

However, very few water molecules ionize in pure water, so the number of hydrogen and hydroxide ions is small. The quantities are usually reported in moles, making it easy to keep track of the numbers of hydrogen and hydroxide ions. One liter of pure water contains 0.0000001 mol of hydrogen ions and an equal number of hydroxide ions. In other words, the concentration of hydrogen ions in a solution of pure water is 0.0000001 mol per liter. This can be written as

$$[H^+] = 1 \times 10^{-7} \text{ mol/L}$$

The brackets around the H^+ signify “the concentration of,” another example of chemical notation.

The hydrogen ion concentration in body fluids is so important to physiological processes that we use a special shorthand to express it. The **pH** of a solution is defined as the negative logarithm of the hydrogen ion concentration in moles per liter. So instead of using the equation $[H^+] = 1 \times 10^{-7} \text{ mol/L}$, we say that the pH of pure water is $-(-7)$, or 7.

Using pH values saves space, but always remember that the pH number is an *exponent* and that the pH scale is logarithmic. For instance, a pH of 6 ($[H^+] = 1 \times 10^{-6}$, or 0.000001 mol/L) means that the concentration of hydrogen ions is *10 times greater than it is at a pH of 7* ($[H^+] = 1 \times 10^{-7}$, or 0.0000001 mol/L). The pH scale ranges from 0 to 14 (**Figure 2-11**).

Pure water has a pH of 7, but as **Figure 2-11** indicates, solutions display a wide range of pH values, depending on the nature of the solutes involved:

- A solution with a pH of 7 is said to be **neutral**, because it contains equal numbers of hydrogen and hydroxide ions.
- A solution with a pH below 7 is **acidic** (a-SID-ik), meaning that it contains more hydrogen ions than hydroxide ions.
- A solution with a pH above 7 is **basic**, or *alkaline* (AL-kuh-lin), meaning that it has more hydroxide ions than hydrogen ions.

The normal pH of blood ranges from 7.35 to 7.45. Abnormal fluctuations in pH can damage cells and tissues by breaking chemical bonds, changing the shapes of proteins, and altering cellular functions. *Acidosis* is an abnormal physiological state caused by low blood pH (below 7.35). A pH below 7 can produce coma. Likewise, *alkalosis* results from an abnormally high pH (above 7.45). A blood pH above 7.8 generally causes uncontrollable and sustained skeletal muscle contractions.

Figure 2-11 The pH Scale Indicates Hydrogen Ion Concentration. The pH scale is logarithmic; an increase or decrease of one unit corresponds to a 10-fold change in H^+ concentration.

✓ Checkpoint

15. Define pH, and explain how the pH scale relates to acidity and alkalinity.
16. What is the significance of pH in physiological systems?

2 See the blue Answers tab at the back of the book.

2-8 Acids, bases, and salts have important physiological roles

Learning Outcome Describe the physiological roles of acids, bases, and salts and the role of buffers in body fluids.

Acids and Bases

The body contains *acids* and *bases* that may cause acidosis or alkalosis, respectively. An **acid** (*acere*, sour) is any solute that dissociates in solution and releases hydrogen ions, lowering the pH. A hydrogen atom that loses its electron consists solely of a proton, so we often refer to hydrogen ions simply as protons, and to acids as *proton donors*. In contrast, a **base** is a solute that removes hydrogen ions from a solution, raising the pH. It acts as a *proton acceptor*. Acids and bases are often identified in terms of *strength*. Strength is a measure of the degree of dissociation of either an acid or a base when it is in solution. There are both strong and weak acids and bases.

A *strong acid* dissociates completely in solution, and the reaction occurs essentially in one direction only. *Hydrochloric acid* (HCl) is a representative strong acid. In water, it ionizes as follows:

The stomach produces this powerful acid to help break down food. Hardware stores sell HCl under the name muriatic acid, for cleaning concrete and swimming pools.

In solution, many bases release a hydroxide ion (OH^-). Hydroxide ions have an attraction for hydrogen ions and react quickly with them to form water molecules. A *strong base* dissociates completely in solution. *Sodium hydroxide*, NaOH, is a strong base. In solution, it releases sodium ions and hydroxide ions:

Strong bases have a variety of industrial and household uses. Drain openers (such as Drano) and lye are two familiar examples.

Weak acids and *weak bases* do not dissociate completely. At equilibrium, a significant number of molecules remain intact in the solution. For the same number of molecules in solution, weak acids and weak bases have less impact on pH than do strong acids and strong bases. *Carbonic acid* (H_2CO_3) is a weak acid found in body fluids. In solution, carbonic acid reversibly dissociates into a hydrogen ion and a *bicarbonate ion*, HCO_3^- :

Salts

A **salt** is an ionic compound containing any cation except a hydrogen ion and any anion except a hydroxide ion. Because they are held together by ionic bonds, many salts dissociate completely in water, releasing cations and anions. For example, sodium chloride (NaCl) dissociates immediately in water, releasing Na^+ and Cl^- . Sodium and chloride ions are the most abundant ions in body fluids. However, many other ions are present in lesser amounts because of the dissociation of other ionic compounds. Ionic concentrations in the body are regulated in ways we describe in Chapters 26 and 27.

The dissociation of sodium chloride does not affect the local concentrations of hydrogen ions or hydroxide ions. For this reason, NaCl, like many salts, is a “neutral” solute. It does not make a solution more acidic or more basic. In contrast, some salts may interact with water molecules and indirectly affect the concentrations of H^+ and OH^- ions. Thus, in some cases, the dissociation of salts makes a solution slightly acidic or slightly basic.

Buffers and pH Control

Buffers are compounds that stabilize the pH of a solution by removing or replacing hydrogen ions. *Buffer systems* usually involve a weak acid and its related salt, which functions as a weak base. For example, the carbonic acid–bicarbonate buffer system consists of carbonic acid and sodium bicarbonate, NaHCO_3 , also known as baking soda. Buffers and buffer systems in body fluids help maintain the pH within normal limits. The pH of several body fluids is included in

Figure 2-11.

The use of antacids is one example of the type of reaction that takes place in buffer systems. Antacids use sodium bicarbonate to neutralize excess hydrochloric acid in the stomach.

Note that the effects of neutralization are most evident when adding a strong acid to a strong base. For example, by adding hydrochloric acid to sodium hydroxide, both the strong acid and the strong base are neutralized:

This neutralization reaction produces water and a salt—in this case, the neutral salt sodium chloride.

✓ Checkpoint

17. Define the following terms: acid, base, and salt.
18. How does an antacid help decrease stomach discomfort?

See the blue Answers tab at the back of the book.

2-9 Living things contain organic compounds made up of monomers, polymers, and functional groups

Learning Outcome Describe monomers and polymers, and the importance of functional groups in organic compounds.

The macromolecules of living things are all organic compounds. Many of these large organic molecules are made up of long chains of carbon atoms linked by covalent bonds. The carbon atoms typically form additional covalent bonds with hydrogen or oxygen atoms and, less commonly, with nitrogen, phosphorus, sulfur, iron, or other elements.

The *macromolecules* of life are complex structures with varied functions and properties. They include carbohydrates, lipids, proteins, and nucleic acids. Each macromolecule is made up of monomer subunits. A **monomer** (MON-ō-mer; *mono-* single + *-mer*, member of a group) is a molecule that can be bonded to other identical molecules to form a **polymer**. Repeating monomers join together through *dehydration synthesis* reactions to form polymers.

The monomers of carbohydrates, lipids, proteins, and nucleic acids are separated, or released, through *hydrolysis reactions*. As a result of such reactions, carbohydrates release monosaccharides, lipids (fats) release fatty acids and glycerol, proteins release amino acids, and nucleic acids release nucleotides. We discuss the structures and functions of these molecules in the next four sections.

Organic compounds are diverse, but certain groupings of atoms, known as *functional groups*, are responsible for the characteristic reactions of a particular compound. Furthermore, these functional groups greatly influence the properties of any molecule of which they are a part. **Table 2-3** details the functional groups in this chapter.

✓ Checkpoint

19. What macromolecules are important to living things?
20. Which functional group acts as an acid?

See the blue Answers tab at the back of the book.

2-10 Carbohydrates contain carbon, hydrogen, and oxygen in a 1:2:1 ratio

Learning Outcome Discuss the structures and functions of carbohydrates.

A **carbohydrate** is an organic molecule that contains carbon, hydrogen, and oxygen in a ratio near 1:2:1. Familiar carbohydrates include the sugars and starches that make up about half of the typical U.S. diet. Carbohydrates typically account for less than 1% of total body weight. Carbohydrates are most important as energy sources that are catabolized. In the following sections, we focus on *monosaccharides*, *disaccharides*, and *polysaccharides*.

Monosaccharides

A **monosaccharide** (mon-ō-SAK-uh-rīd; *mono-*, single + *sakcharon*, sugar), or *simple sugar*, is a carbohydrate with 3 to 7 carbon atoms. Depending on how many carbons it contains, a monosaccharide can be called a *triose* (three carbon atoms), *tetrose* (four carbon atoms), *pentose* (five carbon atoms), *hexose* (six carbon atoms), or *heptose* (seven carbon atoms). The *-ose* ending indicates a sugar. The hexose **glucose** (GLŪ-kōs), $C_6H_{12}O_6$, is the most important metabolic “fuel” in the body. Monosaccharides such as glucose dissolve readily in water and are rapidly distributed throughout the body by blood and other body fluids.

Table 2-3 Important Functional Groups of Organic Compounds

Functional Group	Structural Formula*	Importance	Examples
Amino group $-NH_2$	$\begin{array}{c} \text{H} \\ \\ \text{R}-\text{N} \\ \\ \text{H} \end{array}$	Acts as a base, accepting H^+ , depending on pH; can form bonds with other molecules	Amino acids
Carboxyl group $-COOH$	$\begin{array}{c} \text{OH} \\ \\ \text{R}-\text{C}=\text{O} \end{array}$	Acts as an acid, releasing H^+ to become $R - COO^-$	Fatty acids, amino acids
Hydroxyl group $-OH$	$R - O - H$	May link molecules through dehydration synthesis (condensation); hydrogen bonding between hydroxyl groups and water molecules; affects solubility	Carbohydrates, fatty acids, amino acids
Phosphate group $-PO_4$	$\begin{array}{c} \text{O} \\ \\ \text{R}-\text{O}-\text{P}-\text{O}^- \\ \\ \text{O}^- \end{array}$	May link other molecules to form larger structures; may store energy in high-energy bonds	Phospholipids, nucleic acids, high-energy compounds

*A structural formula shows the covalent bonds within a molecule or functional group (Figure 2-6). The letter R represents the term *R group* and is used to denote the rest of the molecule to which a functional group is attached.

Figure 2-12 The Structures of Glucose. Note that the ring form, the most common form of glucose, is represented with a shorthand shape in later figures: We leave out the carbon atom at five corners of the hexagon, although we do show the oxygen atom at the remaining corner.

2

a The structural formula of the straight-chain form

b The structural formula of the ring form, the most common form of glucose

c A three-dimensional model showing the organization of atoms in the ring form

How many oxygen atoms are shown in each glucose structure?

As shown by two-dimensional diagrams known as *structural formulas*, the atoms in a glucose molecule may form either a straight chain (**Figure 2-12a**) or a ring (**Figure 2-12b**). In the body, the ring form is more common. A three-dimensional model shows the arrangement of atoms in the ring form most accurately (**Figure 2-12c**).

The three-dimensional structure of an organic molecule is an important characteristic because it usually determines the molecule's fate or function. Some molecules have the same molecular formula—in other words, the same types and numbers of atoms—but different structures. Such molecules are called **isomers**. The body usually treats different isomers as distinct molecules. For example, the monosaccharides glucose and fructose are isomers. *Fructose* is a hexose found in many fruits and in secretions of the male reproductive tract. It has the same chemical formula as glucose, $C_6H_{12}O_6$, but the arrangement of its atoms differs from that of glucose. As a result, separate enzymes and reaction sequences control its breakdown and synthesis.

Disaccharides and Polysaccharides

Carbohydrates other than simple sugars are complex molecules composed of monosaccharide building blocks, or monomers. Two monosaccharide monomers joined together form a **disaccharide** (dī-SAK-uh-rīd; *di*-, two). Disaccharides such as *sucrose* (table sugar) have a sweet taste and, like monosaccharides, are quite soluble in water.

The formation of sucrose involves a dehydration synthesis reaction (**Figure 2-13a**). Recall that dehydration synthesis reactions link molecules together by the removal of a water

Figure 2-13 The Formation and Breakdown of Complex Sugars.

a **Formation of the disaccharide sucrose through dehydration synthesis.** During dehydration synthesis, 2 molecules are joined by the removal of a water molecule.

b **Breakdown of sucrose into simple sugars by hydrolysis.** Hydrolysis reverses the steps of dehydration synthesis; a complex molecule is broken down by the addition of a water molecule.

molecule. The breakdown of sucrose into simple sugars is an example of hydrolysis, or breakdown by the addition of a water molecule (**Figure 2-13b**). Hydrolysis is the functional opposite of dehydration synthesis.

Many foods contain disaccharides, but all carbohydrates except monosaccharides must be broken apart through hydrolysis before they can provide useful energy. Most popular junk foods (high in calories but otherwise lacking in nutritional content), such as candies and sodas, are full of monosaccharides (commonly fructose) and disaccharides (generally sucrose). Some people cannot tolerate sugar for medical reasons. Others avoid it to control their weight (because excess sugars are converted to fat for long-term storage). Many of these people use *artificial sweeteners* in their foods and beverages. These compounds have a very sweet taste, but they either cannot be broken down in the body or are used in insignificant amounts.

More complex carbohydrates result when repeated dehydration synthesis reactions add additional monosaccharides or disaccharides. These large molecules (polymers) are called **polysaccharides** (pol-ē-SAK-uh-rīdz; *poly-*, many). Polysaccharide chains can be straight or highly branched. *Cellulose*, a structural component of many plants, is a polysaccharide that our bodies cannot digest because the linkages between the glucose molecules cannot be split by enzymes in the body. Foods such as celery, which contains cellulose, water, and little else, contribute fiber to digestive wastes but do not provide a source of energy.

Starches are large polysaccharides formed from glucose molecules. Most starches are manufactured by plants. The digestive tract can break these molecules into monosaccharides. Starches such as those in potatoes and grains are a major dietary energy source.

The polysaccharide **glycogen** (GLĭ-kō-jen), or *animal starch*, has many side branches consisting of chains of glucose molecules (**Figure 2-14**). Like most other starches, glycogen does not dissolve in water or other body fluids. Muscle cells make and store glycogen. When muscle cells have a high demand for glucose, glycogen molecules are broken down. When the need is low, these cells absorb glucose from the bloodstream and rebuild glycogen reserves. **Table 2-4** summarizes information about carbohydrates.

Figure 2-14 The Structure of the Polysaccharide

Glycogen. Liver and muscle cells store glucose as the polysaccharide glycogen, a long, branching chain of glucose molecules.

✓ Checkpoint

21. Plant starch and glycogen are both polysaccharides. What monomer do they have in common?

See the blue Answers tab at the back of the book.

2-11 Lipids often contain a carbon-to-hydrogen ratio of 1:2

Learning Outcome Discuss the structures and functions of lipids.

Like carbohydrates, **lipids** (*lipos*, fat) contain carbon, hydrogen, and oxygen, and the carbon-to-hydrogen ratio is near 1:2. However, lipids contain much less oxygen than do carbohydrates with the same number of carbon atoms.

Table 2-4 Carbohydrates in the Body

Structural Class	Examples	Primary Function	Remarks
Monosaccharides (simple sugars)	Glucose, fructose	Energy source	Manufactured in the body and obtained from food; distributed in body fluids
Disaccharides	Sucrose, lactose, maltose	Energy source	Sucrose is table sugar, lactose is in milk, and maltose is malt sugar found in germinating grain; all must be broken down to monosaccharides before absorption
Polysaccharides	Glycogen	Storage of glucose	Glycogen is in animal cells; other starches and cellulose are within or around plant cells

The hydrogen-to-oxygen ratio is therefore very large. For example, a representative lipid, such as lauric acid (found in coconut, laurel, and palm kernel oils), has a formula of $C_{12}H_{24}O_2$. Lipids may also contain small quantities of phosphorus, nitrogen, or sulfur. Familiar lipids include *fats*, *oils*, and *waxes*. Most lipids are hydrophobic, or insoluble in water, but special transport mechanisms carry them into the bloodstream.

Lipids form essential structural components of all cells. In addition, lipid deposits are important as energy reserves. On average, lipids provide twice as much energy as carbohydrates do, gram for gram, when broken down in the body. When the supply of lipids exceeds the demand for energy, the excess is stored in fat deposits. For this reason, there has been great interest in developing *fat substitutes* that provide less energy but have the same desirable taste and texture as the fats found in many foods.

Lipids normally make up 12–24% of the total body weight of adults. Many kinds of lipids exist in the body. We consider five classes of lipids: *fatty acids*, *eicosanoids*, *glycerides*, *steroids*, and *phospholipids* and *glycolipids*.

Fatty Acids

Fatty acids are long carbon chains with hydrogen atoms attached. They are one of the monomers of lipids. One end of the carbon chain is always attached to a *carboxyl* (kar-BOK-sil) group, $-COOH$ (Table 2-3). The name *carboxyl* should help you remember that a carbon and a hydroxyl ($-OH$) group are the important structural features of fatty acids. The carbon chain attached to the carboxyl group is known as the *hydrocarbon tail* of the fatty acid. Figure 2-15a shows a representative fatty acid, *lauric acid*.

Fatty acids have a very limited solubility in water. When a fatty acid is in solution, only the carboxyl end associates with water molecules, because that is the only hydrophilic portion of the molecule. The hydrocarbon tail is hydrophobic. In general, the longer the hydrocarbon tail, the lower the solubility of the molecule.

Fatty acids may be either saturated or unsaturated (Figure 2-15b). These terms refer to the number of hydrogen atoms bound to the carbon atoms in the hydrocarbon tail. In a *saturated* fatty acid, each carbon atom in the tail has four single covalent bonds (Figure 2-15a). Within the tail, two of those bonds bind adjacent carbon atoms, and the other two bind hydrogen atoms. The carbon atom at the end of the tail binds three hydrogen atoms. In an *unsaturated* fatty acid, one or more of the single covalent bonds between the carbon atoms have been replaced by a double covalent bond. As a result, the carbon atoms involved will each bind only one hydrogen atom rather than two. This changes the shape of the hydrocarbon tail, giving it a sharp bend, as shown in Figure 2-15b. The change also affects the way the fatty acid is metabolized.

Figure 2-15 Fatty Acids.

- a** Lauric acid shows two structural characteristics common to all fatty acids: a long chain of carbon atoms and a carboxyl group ($-COOH$) at one end.

- b** A fatty acid is either saturated (has single covalent bonds only) or unsaturated (has one or more double covalent bonds). The presence of a double bond causes a sharp bend in the molecule.

What type of bond does an unsaturated fatty acid contain that a saturated fatty acid does not?

A *monounsaturated* fatty acid has a single double bond in the hydrocarbon tail. A *polyunsaturated* fatty acid contains two or more double bonds.

Eicosanoids

Eicosanoids (ī-KŌ-sa-noydz) are lipids derived from *arachidonic* (ah-rak-i-DON-ik) acid, a fatty acid that must be absorbed in the diet because the body cannot synthesize it. The two

Figure 2-16 Prostaglandins. Prostaglandins contain 20 carbon atoms and a five-carbon ring.

major classes of eicosanoids are *leukotrienes* and *prostaglandins*. **Leukotrienes** (lū-kō-TRĭ-ēnz) are produced mostly by cells involved with coordinating the responses to injury or disease.

Prostaglandins (pros-tuh-GLAN-dinz) are short-chain fatty acids in which five of the carbon atoms are joined in a ring (**Figure 2-16**). These compounds are released by cells to coordinate or direct local cellular activities, and they are extremely powerful even in small quantities. Virtually all tissues synthesize and respond to them. The effects of prostaglandins vary with their structure and their release site. Prostaglandins released by damaged tissues, for example, stimulate nerve endings and produce the sensation of pain. Those released in the uterus help trigger the start of labor contractions.

The body uses several types of chemical messengers. Those that are produced in one part of the body and have effects on distant parts are called *hormones*. Hormones are distributed throughout the body in the bloodstream, but most prostaglandins affect only the area in which they are produced. As a

result, prostaglandins are often called *local hormones*. The distinction is not a rigid one, however, as some prostaglandins also enter the bloodstream and affect other areas. Hormones and prostaglandins are discussed in Chapter 18.

Glycerides

Unlike monosaccharides, individual fatty acids cannot be strung together in a chain by dehydration synthesis to form a polymer. But they can be attached to a modified simple sugar, **glycerol** (GLIS-er-ol), through a similar reaction. The result is a lipid known as a **glyceride** (GLIS-er-ĭd). Dehydration synthesis reactions can produce a **monoglyceride** (mon-ō-GLIS-er-ĭd), consisting of glycerol plus one fatty acid. Subsequent reactions can yield a **diglyceride** (glycerol + two fatty acids) and then a **triglyceride** (glycerol + three fatty acids), as in **Figure 2-17**. Hydrolysis breaks the glycerides into fatty acids and glycerol (monomers). Comparing **Figure 2-17** with **Figure 2-13** shows that dehydration synthesis and hydrolysis operate the same way, whether the molecules involved are carbohydrates or lipids.

Triglycerides, also known as *triacylglycerols* or *neutral fats*, are important lipid polymers. They have the following important functions:

- **Energy Source.** Fat deposits in the body represent a significant energy reserve. In times of need, the triglycerides are taken apart by hydrolysis, yielding fatty acids that can be broken down to provide energy.

+ Clinical Note Too Sweet on Sugar?

A baby's first and favorite taste is sweet: breast milk is rich in *lactose* (milk sugar), a disaccharide of glucose and galactose. This preference for sweet persists throughout life. Even in people with poor appetites, ice cream is often more palatable than steamed spinach. Manufacturers of processed foods know this.

When heart disease became endemic in the United States, holding first place as the killer of Americans, the medical community advocated a low-fat diet for heart health. Artery-clogging fats were removed from manufactured foods—such as cookies, soups, and other boxed, bagged, and frozen products—and replaced with sugar for flavor and mouth appeal.

AVOID TOO MUCH:	
5%	Saturated Fat 1g
	Trans Fat 0g
0%	Cholesterol 0mg
7%	Sodium 160mg
	Added Sugars 0g

The sweetening of the American diet has wreaked a new kind of havoc on American health. Dental hygienists see more *dental caries* (cavities). Obesity is climbing at an alarming rate. Grade-school children are developing more *type 2 diabetes*, formerly called “adult-onset diabetes.” These serious and potentially fatal diseases generally did not appear until a person had lived several decades with a poor lifestyle or limited access to high-quality food.

Glucose is a necessary nutrient. Our body's cells depend on it for fuel; our neurons (brain cells) require it. However, we should meet our glucose needs through complex carbohydrates, or polysaccharides (such as glycogen). In contrast to simple sugars, complex carbohydrates are digested slowly by decomposition reactions in the digestive tract. The component monosaccharides of glucose are released and absorbed gradually, maintaining a steady blood glucose level. In turn, the pancreas is signaled only as needed to make the protein hormone *insulin*, which stimulates the transport of glucose into the body's cells. Complex carbohydrates promote satiety (fullness) and support healthy sugar metabolism.

Figure 2-17 Triglyceride Formation. The formation of a triglyceride involves the attachment of fatty acids to a glycerol molecule through dehydration synthesis. In this example, a triglyceride is formed by the attachment of one unsaturated and two saturated fatty acids to a glycerol molecule.

? What makes fatty acid 3 an unsaturated fatty acid?

- **Insulation.** Fat deposits under the skin serve as insulation, slowing heat loss to the environment. Heat loss across a layer of lipids is only about one-third of the heat loss through other tissues.
- **Protection.** A fat deposit around a delicate organ such as a kidney provides a cushion that protects against bumps or jolts.

Triglycerides are stored in the body as lipid droplets within cells. The droplets absorb and accumulate lipid-soluble vitamins, drugs, or toxins that appear in body fluids. This accumulation has both positive and negative effects. For example, the body's lipid reserves retain both valuable lipid-soluble vitamins (A, D, E, K) and potentially dangerous lipid-soluble pesticides, such as the now-banned DDT.

Steroids

Steroids are large lipid molecules that share a distinctive four-ring carbon structure (**Figure 2-18**). They differ in the functional groups that are attached to this basic framework. The steroid **cholesterol** (kō-LES-ter-ol; *chole-*, bile + *stereos*, solid) and related steroids are important for several reasons:

- The outer boundary of all animal cells, called a plasma membrane, contains cholesterol (**Figure 2-18a**). Cells need cholesterol to maintain their plasma membranes, as well as for cell growth and division.
- Steroid hormones are involved in the regulation of sexual function. Examples include the sex hormones *estrogen* and *testosterone* (**Figure 2-18b,c**).
- Steroid hormones are important in the regulation of tissue metabolism and mineral balance. Examples include *corticosteroids* from the adrenal cortex, which play a role in carbohydrate and protein metabolism, and *calcitriol* from the kidneys, a hormone important in the regulation of the body's calcium ion concentrations.
- Steroid derivatives called *bile salts* are required for the normal processing of dietary fats. The liver produces bile salts and secretes them in bile. They interact with lipids in the intestinal tract and assist with the digestion and absorption of lipids.

The body obtains cholesterol in two ways: (1) by absorbing it from animal products in the diet and (2) by synthesizing it.

Figure 2-18 Steroids Have a Complex Four-Ring Structure. Individual steroids differ in the side chains attached to the carbon rings.

Liver, meat, shellfish, and egg yolks are especially rich dietary sources of cholesterol. People with *hypercholesterolemia*, a condition characterized by very high levels of blood cholesterol, have an increased risk of developing a form of heart disease called coronary artery disease (CAD). In CAD, excess cholesterol deposits on arterial walls, forming plaques that obstruct blood flow to the heart. Currently, it is suggested that a healthy person consume no more than 300 mg of cholesterol per day, and others with diabetes, high cholesterol, or heart disease should consume no more than 200 mg per day. Unfortunately, the blood cholesterol level can be difficult to control by dietary restriction alone because the body can synthesize cholesterol as well. In fact, the body makes more than enough, so strict vegetarians do not need to eat animal products to ensure adequate amounts of cholesterol.

Phospholipids and Glycolipids

Phospholipids (FOS-fō-lip-idz) and **glycolipids** (GLĪ-kō-lip-idz) are structurally related, and our cells can synthesize both types of lipids, primarily from fatty acids. In a *phospholipid*, a *phosphate group* (PO_4^{3-}) links a diglyceride to a nonlipid group (**Figure 2-19a**). There are different types of phospholipids; the one shown in this figure is lecithin. In a *glycolipid*, a carbohydrate is attached to a diglyceride (**Figure 2-19b**). Note that placing *-lipid* last in these names indicates that the molecule consists primarily of lipid.

The long hydrocarbon tails of phospholipids and glycolipids are hydrophobic, but the opposite ends, the nonlipid *heads*, are hydrophilic. In water, large numbers of these molecules tend to form droplets, or *micelles* (mĪ-SELZ), with the hydrophilic portions on the outside (**Figure 2-19c**). Most meals contain a mixture of lipids and other organic molecules, and micelles form as the food breaks down in the digestive tract. In addition to phospholipids and glycolipids, micelles may contain other insoluble lipids, such as steroids, glycerides, and long-chain fatty acids.

Phospholipids and glycolipids (as well as cholesterol) are called *structural lipids* because they help form and maintain

intracellular structures called membranes. At the cellular level, *membranes* are sheets or layers composed mainly of lipids. For example, the plasma membrane surrounding each cell is composed primarily of phospholipids. It separates the aqueous solution inside the cell from the aqueous solution outside the cell. Also, various internal membranes subdivide the interior of the cell into specialized compartments, each with a distinctive chemical nature and, as a result, a different function.

The five types of lipids and their characteristics are summarized in **Table 2-5**.

23. Which lipids are found in human plasma membranes?

See the blue Answers tab at the back of the book.

2-12 Proteins contain carbon, hydrogen, oxygen, and nitrogen and are formed from amino acids

Learning Outcome Discuss the structures and functions of proteins.

Proteins are the most abundant organic molecules in the human body and in many ways the most important. The human body contains many different proteins, and they account for about 20% of total body weight. All proteins contain carbon, hydrogen, oxygen, and nitrogen. Smaller quantities of sulfur and phosphorus may also be present. *Amino acids* are simple organic compounds (monomers) that combine to form proteins (polymers).

Proteins carry out a variety of essential functions, which we can group into the following major categories:

- **Support.** *Structural proteins* create a three-dimensional framework for the body. They provide strength, organization, and support for cells, tissues, and organs.

Table 2-5 Representative Lipids and Their Functions in the Body

Lipid Type	Example(s)	Primary Functions	Remarks
Fatty acids	Lauric acid	Energy source	Absorbed from food or synthesized in cells; transported in the blood
Eicosanoids	Prostaglandins, leukotrienes	Chemical messengers coordinating local cellular activities	Prostaglandins are produced in most body tissues
Glycerides	Monoglycerides, diglycerides, triglycerides	Energy source, energy storage, insulation, and physical protection	Stored in fat deposits; must be broken down to fatty acids and glycerol before they can be used as an energy source
Steroids	Cholesterol	Structural component of plasma membranes, hormones, digestive secretions in bile	All have the same four-carbon ring framework
Phospholipids, glycolipids	Lecithin (a phospholipid)	Structural components of plasma membranes	Derived from fatty acids and nonlipid components

Figure 2–19 Phospholipids and Glycolipids.

- **Movement.** *Contractile proteins* bring about muscular contraction. Related proteins are responsible for the movement of individual cells.
- **Transport.** Special *transport proteins* bind many substances for transport in the blood, including insoluble lipids, respiratory gases, special minerals such as iron, and several hormones. These substances would not otherwise be transported in the blood. Other specialized proteins move materials from one part of a cell to another.

- **Buffering.** Proteins provide a buffering action, which helps prevent dangerous changes in the pH of body fluids.
- **Metabolic Regulation.** Many proteins are enzymes, which speed up chemical reactions in cells. The sensitivity of enzymes to environmental factors such as temperature and pH is extremely important in controlling the pace and direction of metabolic reactions.
- **Coordination and Control.** Protein hormones can influence the metabolic activities of every cell in the body or affect the function of specific organs or organ systems.

- **Defense.** Proteins defend the body in many ways. The tough, waterproof proteins of the skin, hair, and nails protect the body from environmental hazards. Proteins called *antibodies* help protect us from disease by taking part in the *immune response*. Special *clotting proteins* restrict bleeding after an injury.

Protein Structure

Proteins are organic polymers that consist of long chains of similar organic molecules called **amino acids**. Twenty different amino acid monomers occur in significant quantities in the body. All 20 amino acids are small, water-soluble molecules. A typical protein contains 1000 amino acids, while the largest protein complexes have 100,000 or more.

Each amino acid consists of five parts (**Figure 2-20**):

- a central carbon atom,
- a hydrogen atom,
- an *amino group* ($-\text{NH}_2$),
- a carboxyl group ($-\text{COOH}$),
- an *R group* (a variable *side chain* of one or more atoms that identifies a specific amino acid).

The name *amino acid* refers to the presence of the amino group and the carboxyl group, which all amino acids have in common. At physiological pH levels, the carboxyl group can act as an acid by releasing a hydrogen ion to become a *carboxyl ion* (COO^-). The amino group can act as a base by accepting a hydrogen ion, to become an amino ion ($-\text{NH}_3^+$). The result is a molecule that has both positive and negative charges, but a net charge of zero. Such molecules are called *zwitterions*, derived from the German word that means “hybrid.”

A protein begins to form as amino acids are strung together into long chains. **Figure 2-21** shows how dehydration synthesis can link two representative amino acids: *glycine* and *alanine*. This reaction creates a covalent bond between the carboxyl group of one amino acid and the amino group of another. Such a bond is known as a **peptide bond**. Molecules

Figure 2-20 Amino Acids. Each amino acid consists of a central carbon atom to which four different groups are attached: a hydrogen atom, an amino group ($-\text{NH}_2$), a carboxyl group ($-\text{COOH}$), and a variable side group designated as R.

Figure 2-21 The Formation of Peptide Bonds. Peptides form as dehydration synthesis creates a peptide bond between the carboxyl group of one amino acid and the amino group of another. In this example, a peptide bond links the amino acids glycine (for which $\text{R} = \text{H}$) and alanine ($\text{R} = \text{CH}_3$) to form a dipeptide.

consisting of amino acids held together by peptide bonds are called **peptides**. The molecule created in this example is called a *dipeptide* because it contains two amino acids.

The chain can be lengthened by the addition of more amino acids. Attaching a third amino acid produces a *tripeptide*. Tripeptides and larger peptide chains are called **polypeptides**. Polypeptides with more than 100 amino acids are usually called proteins. Familiar proteins include *hemoglobin* in red blood cells, *collagen* in skin, bones, and muscles, and *keratin* in fingernails and hair.

The different atoms of the R groups distinguish one amino acid from another, giving each its own chemical properties. For example, different R groups are polar, nonpolar, or electrically charged. Amino acids with nonpolar R groups are hydrophobic, whereas amino acids with polar R groups that form hydrogen bonds with water are hydrophilic. Amino acids with electrically charged R groups are strongly hydrophilic. The properties of the R groups contribute to the overall shape and function of proteins.

Protein Shape

The characteristics of a particular protein are determined in part by the R groups on its amino acids. But the properties of a protein are more than just the sum of the properties of its parts, for polypeptides can have highly complex shapes that are important to their function. Proteins can have four levels of structural complexity (**Figure 2-22**):

- 1. Primary structure** is the sequence of amino acids along the length of a single polypeptide (**Figure 2-22a**). Peptide bonds are responsible for the primary structure of proteins.
- 2. Secondary structure** is the shape that results from the presence of hydrogen bonds between atoms at different parts of the polypeptide chain. Hydrogen bonding may create either an *alpha helix* (simple spiral) or *beta sheet* (a flat

pleated sheet) (**Figure 2-22b**). Which one forms depends on where hydrogen bonding takes place between the sequence of amino acids in the polypeptide chain. The alpha helix is the more common form, but a given polypeptide chain may have both helical and pleated sections. Ribbon diagrams are used to represent the three-dimensional structure of proteins. An alpha helix appears as a coiled ribbon, beta

Figure 2-22 Protein Structure.

sheets as arrows, and less-structured polypeptide chains as narrow ribbons or tubes.

3. **Tertiary structure** is the complex coiling and folding that gives a protein its final three-dimensional shape (**Figure 2-22c**). Tertiary structure results primarily from hydrophobic and hydrophilic interactions between the R groups of the polypeptide chain and the surrounding water molecules, and to a lesser extent from interactions between the R groups of amino acids in different parts of the molecule. Most such interactions are relatively weak. One, however, is very strong: the *disulfide bond*, a covalent bond that may form between the sulfur atoms of two molecules of the amino acid *cysteine* located at different sites along the chain (not shown). Disulfide bonds create permanent loops or coils in a polypeptide chain.
4. **Quaternary structure** is the interaction between individual polypeptide chains to form a protein complex (**Figure 2-22d**). Each of the polypeptide subunits has its own secondary and tertiary structures. For example, the protein *hemoglobin* contains four subunits. In **Figure 2-22d**, the polypeptide subunits with the same color (blue or purple) have the same structure. The hemoglobin in red blood cells binds and transports oxygen. *Collagen*, composed of three windings of alpha-helical polypeptides, is the most abundant structural protein and is found in skin, bones, muscles, cartilages, and tendons. Collagen fibers form the framework that supports cells in most tissues. In *keratin*, two alpha-helical polypeptides are wound together like the strands of a rope. Keratin is the tough, water-resistant protein at the surface of the skin and in nails and hair.

Globular and Fibrous Proteins

Proteins fall into two general structural classes based on their overall shape and properties:

- **Globular proteins** are compact, generally rounded, and soluble in water. Many enzymes, hormones, and other molecules that circulate in the bloodstream are globular proteins. These proteins can function only if they remain in solution. The unique shape of each globular protein comes from its tertiary structure. Hemoglobin and *myoglobin*, a protein in muscle cells, are both globular proteins. The enzymes that control chemical reactions inside cells are also globular proteins.
- **Fibrous proteins** form extended sheets or strands. Fibrous proteins are tough, durable, and generally insoluble in water. They usually play structural roles in the body. Their shapes are usually due to secondary structure (for proteins with the pleated-sheet form) or quaternary structure (as we just described for collagen and keratin).

Protein Shape and Function

The shape of a protein determines its functional characteristics, and the sequence of amino acids ultimately determines its shape. The 20 amino acids can be linked in an astonishing number of combinations, creating proteins of enormously varied shape and function. Changing only one of the 10,000 or more amino acids in a protein can significantly alter the way the protein functions. For example, several cancers and *sickle cell anemia*, a blood disorder, result from changing just a single amino acid in the amino acid sequences of complex proteins.

The tertiary and quaternary shapes of complex proteins depend not only on their amino acid sequence, but also on the local environmental conditions. Small changes in the ionic composition, temperature, or pH of their surroundings can affect the function of proteins. Protein shape can also be affected by hydrogen bonding to other molecules in solution. The significance of these factors is most striking when we consider enzymes, for these proteins are essential to the metabolic operations in every one of our cells.

Enzyme Function

Enzymes are among the most important of all the body's proteins. As noted earlier in this chapter, enzymes catalyze the chemical reactions that sustain life. Almost everything that happens inside the human body does so because a specific enzyme makes it possible.

The reactants in enzymatic reactions are called **substrates**. As in other types of chemical reactions, the interactions among substrates yield specific products. Before an enzyme can function as a catalyst—accelerating a chemical reaction without itself being permanently changed or consumed—the substrates must bind to a special region of the enzyme. This region is called the **active site**. It is typically a groove or pocket into which one or more substrates nestle, like a key fitting into a lock. Weak electrical attractive forces, such as hydrogen bonding, reinforce the physical fit. The tertiary or quaternary structure of the enzyme molecule determines the shape of the active site. Although enzymes are proteins, any organic or inorganic compound that will bind to the active site can be a substrate.

Figure 2-23 presents one example of enzyme structure and function. Substrates bind to the enzyme at its active site (1). Substrate binding produces an *enzyme–substrate complex* (2). Substrate binding typically produces a temporary, reversible change in the shape of the enzyme that may place physical stresses on the substrate molecules, leading to product formation (3). The product is then released, freeing the enzyme to repeat the process (4).

Enzymes work quickly, cycling rapidly between substrates and products. For example, an enzyme providing energy during a muscular contraction performs its reaction sequence 100 times per second. Hydrolytic enzymes can work even faster, breaking down almost 20,000 molecules a second!

Figure 2-23 A Simplified View of Enzyme Structure and Function. Each enzyme contains a specific active site somewhere on its exposed surface.

Figure 2-23 shows an enzyme that catalyzes a synthesis reaction. Other enzymes may catalyze decomposition reactions, reversible reactions, or exchange reactions. Regardless of the reaction they catalyze, all enzymes share the basic characteristics of specificity, saturation limits, and regulation:

- **Specificity.** Each enzyme catalyzes only one type of reaction, a characteristic called **specificity**. An enzyme's specificity is due to the ability of its active sites to bind only to substrates with specific shapes and charges. For this reason, differences in enzyme structure that do not affect the active site and do not change the response of the enzyme to substrate binding do not affect enzyme function. Such enzyme variants are called *isozymes*.
- **Saturation Limits.** The rate of an enzymatic reaction is directly related to the concentrations of substrate molecules and enzymes. An enzyme molecule must encounter appropriate substrates before it can catalyze a reaction. The higher the substrate concentration, the more frequent these encounters. When substrate concentrations are high enough that every enzyme molecule is cycling through its reaction sequence at top speed, further increases in substrate concentration will not affect the rate of reaction unless additional enzyme molecules are provided. The substrate concentration required to reach the maximum rate of reaction is called the *saturation limit*. An enzyme that has reached its saturation limit is said to be **saturated**. To increase the reaction rate further, the cell must increase the number of enzyme molecules available. This is one important way that cells promote specific reactions.
- **Regulation.** Each cell contains an assortment of enzymes, and any specific enzyme may be active under one set of conditions and inactive under another. Virtually

anything that changes the tertiary or quaternary shape of an enzyme can turn it "on" or "off" and in this way control reaction rates inside the cell. Because the shape change is immediate, enzyme activation or inactivation is an important method of short-term control over reaction rates and metabolic pathways. Here we consider only one example of enzyme regulation: the presence or absence of *cofactors*.

Cofactors and Enzyme Function

A **cofactor** is an ion or a molecule that must bind to an enzyme before substrates can also bind. Without a cofactor, the enzyme is intact but nonfunctional. With the cofactor, the enzyme can catalyze a specific reaction. Examples of ionic cofactors include calcium ion (Ca^{2+}) and magnesium ion (Mg^{2+}), which bind at the enzyme's active site. Cofactors may also bind at other sites, if they produce a change in the shape of the active site that makes substrate binding possible.

Coenzymes are nonprotein organic molecules that function as cofactors. Our bodies convert many vitamins into essential coenzymes. *Vitamins*, detailed in Chapter 25, are organic nutrients structurally related to lipids or carbohydrates, but have unique functional roles. Because the human body cannot synthesize most of the vitamins it needs, they must be obtained from the diet.

Temperature and pH Affect Enzyme Function

Each enzyme works best at specific temperatures and pH values. As temperatures increase, protein shape changes and enzyme function changes. Eventually, the protein undergoes **denaturation**, a change in tertiary or quaternary structure that makes it nonfunctional. For example, permanent denaturation occurs when an egg is fried. As the temperature rises, the proteins in

the egg white denature. Eventually, the proteins become completely and irreversibly denatured, forming an insoluble white mass. In the body, death occurs at very high body temperatures (above 43°C, or 110°F) because structural proteins and enzymes soon denature, causing irreparable damage to organs and organ systems.

Enzymes are equally sensitive to changes in pH. *Pepsin*, an enzyme that breaks down food proteins in the stomach, works best at a pH of 2.0 (strongly acidic). The small intestine contains *trypsin*, another protein-degrading enzyme. Trypsin works only in an alkaline environment, with an optimum pH of 7.7 (weakly basic).

Glycoproteins and Proteoglycans

Glycoproteins (GLĪ-kō-prō-tēnz) and **proteoglycans** (prō-tē-ō-GLĪ-kanz) are combinations of protein and carbohydrate molecules. Glycoproteins are large proteins with small carbohydrate groups attached. These molecules may function as enzymes, antibodies, hormones, or protein components of plasma membranes. Glycoproteins in plasma membranes play a major role in identifying normal versus abnormal cells. They are also important in the immune response (Chapter 22). Glycoprotein secretions called *mucins* absorb water to form **mucus**. Mucus coats and lubricates the surfaces of the reproductive and digestive tracts.

Proteoglycans are large polysaccharide molecules linked by polypeptide chains. Proteoglycans bind adjacent cells together and give tissue fluids a viscous (syrupey) consistency.

2-13 DNA and RNA are nucleic acids

Learning Outcome Discuss the structures and functions of nucleic acids.

Nucleic (nū-KLĀ-ik) **acids** are large organic molecules composed of carbon, hydrogen, oxygen, nitrogen, and phosphorus. Nucleic acids store and process information at the molecular level inside cells. The two classes of nucleic acid molecules are **deoxyribonucleic** (dē-oks-ē-rī-bō-nū-KLĀ-ik) **acid (DNA)** and **ribonucleic** (rī-bō-nū-KLĀ-ik) **acid (RNA)**. These two classes of nucleic acids differ in composition, structure, and function.

The primary role of nucleic acids is to store and transfer information—specifically, information essential to the synthesis of proteins within our cells. The DNA in our cells encodes the information needed to build proteins, while several forms

of RNA cooperate to build specific proteins using the information provided by DNA.

DNA contains the instructions for making proteins with correct shapes and therefore correct functions. Those proteins then control our inherited characteristics. For example, by directing the synthesis of structural proteins, DNA determines all of our physical characteristics, including eye color, hair color, and blood type. By directing the synthesis of many functional proteins, including enzymes, DNA regulates all aspects of cellular metabolism, including the creation and destruction of lipids, carbohydrates, and other vital molecules.

In this section, we look at how nucleic acids are structured, and the similarities and differences between DNA and RNA. In Chapter 3 we detail the ways that DNA and RNA work together.

Structure of Nucleic Acids

A nucleic acid consists of one or two long chains of repeating subunits. The individual subunits (monomers) of the chain are called **nucleotides**. Each nucleotide has three parts (**Figure 2-24a**): (1) a pentose (five-carbon sugar) attached to both, (2) a phosphate group and (3) a **nitrogenous** (nitrogen-containing) **base**. The pentose is either **ribose** (in RNA) or **deoxyribose** (in DNA).

Five nitrogenous bases occur in nucleic acids: **adenine (A)**, **guanine (G)**, **cytosine (C)**, **thymine (T)**, and **uracil (U)**. Adenine and guanine are double-ringed molecules called **purines** (**Figure 2-24b**). The other three bases are single-ringed molecules called **pyrimidines** (**Figure 2-24c**). Both RNA and DNA contain adenine, guanine, and cytosine. Uracil occurs only in RNA and thymine occurs only in DNA.

A nucleotide forms when a phosphate group binds to a pentose already attached to a nitrogenous base. A nucleic acid forms when nucleotides are joined by dehydration synthesis, which attaches the phosphate group of one nucleotide to the sugar of another. The “backbone” of a nucleic acid molecule is a linear sugar-to-phosphate-to-sugar sequence, with the nitrogenous bases projecting to one side.

Comparison of RNA and DNA

In both DNA and RNA, it is the sequence of nitrogenous bases that carries the information about how to make proteins. However, there are other important structural differences between the two types of nucleic acids. A molecule of RNA consists of a single chain of nucleotides (**Figure 2-25a**). Its shape depends on the order of the nucleotides and the interactions among them. Our cells have various forms of RNA with different shapes and functions. As described in Chapter 3, protein synthesis requires three types of RNA: (1) *messenger RNA* (mRNA), (2) *transfer RNA* (tRNA), and (3) *ribosomal RNA* (rRNA). There are also other types of RNA whose roles are under active research.

Figure 2-24 Nucleotides and Nitrogenous Bases.**Figure 2-25** The Structure of Nucleic Acids. The nucleic acids RNA and DNA are long chains of nucleotides.

What structural differences make adenine and guanine different from cytosine, thymine, and uracil?

A DNA molecule consists of a *pair* of nucleotide chains, with two sugar-phosphate backbones on the outside and the nitrogenous bases projecting inward (**Figure 2-25b**). Hydrogen bonding between opposing nitrogenous bases holds the two strands together. The shapes of the nitrogenous bases allow adenine to bond only to thymine, and cytosine to bond only to guanine. As a result, the combinations adenine–thymine (A–T) and cytosine–guanine (C–G) are known as **complementary base pairs**, and the two nucleotide chains of the DNA molecule are known as **complementary strands**. The two strands of DNA twist around one another in a double helix that resembles a spiral staircase. Each step of the staircase corresponds to one complementary base pair.

Table 2-6 Comparison of RNA and DNA

Characteristic	RNA	DNA
Sugar	Ribose	Deoxyribose
Nitrogenous bases	Adenine (A) Guanine (G) Cytosine (C) Uracil (U)	Adenine Guanine Cytosine Thymine (T)
Number of nucleotides in typical molecule	Varies from fewer than 100 nucleotides to about 50,000	Always more than 45 million
Shape of molecule	Varies with hydrogen bonding along the length of the strand; three main types (mRNA, rRNA, tRNA)	Paired strands coiled in a double helix
Function	Performs protein synthesis as directed by DNA	Stores genetic information that controls protein synthesis

Through a sequence of events described in Chapter 3, the cell uses one of the two complementary DNA strands to provide the information needed to synthesize a specific protein. **Table 2-6** summarizes our comparison of RNA and DNA.

2-14 ATP is a high-energy compound used by cells

Learning Outcome Discuss the structures and functions of high-energy compounds.

To perform their vital functions, cells must use energy, which they obtain by breaking down organic substrates (catabolism). To be useful, that energy must be transferred from molecule to molecule or from one part of the cell to another.

The usual method of energy transfer involves the creation and breakdown of high-energy bonds by enzymes within cells. A *high-energy bond* is a covalent bond whose breakdown releases energy the cell can use directly. In our cells, a high-energy bond generally binds a phosphate group (PO_4^{3-}) to an organic molecule. The product with such a bond is called a **high-energy compound**. Most high-energy compounds are derived from nucleotides, the building blocks of nucleic acids (**Figure 2-26**).

The process of attaching a phosphate group to another molecule is called **phosphorylation** (fos-for-i-LÄ-shun). This process does not necessarily produce high-energy bonds. For example, in the synthesis of sucrose, a phosphate group is first attached to glucose. The creation of a high-energy compound

requires (1) a phosphate group, (2) enzymes capable of catalyzing the reactions involved, and (3) suitable organic substrates to which the phosphate can be added.

The most important such substrate is the nucleotide **adenosine monophosphate (AMP)**, which already contains one phosphate group. Attaching a second phosphate group produces **adenosine diphosphate (ADP)**. A significant

Figure 2-26 The Structure of ATP. A molecule of ATP is formed by attaching two phosphate groups to the nucleotide adenosine monophosphate. These two phosphate groups are connected by high-energy bonds incorporating energy released by catabolism. Cells most often obtain quick energy to power cellular operations by removing one phosphate group from ATP, forming ADP (adenosine diphosphate). ADP can later be reconverted to ATP, and the cycle repeated.

How many phosphorylation reactions does AMP undergo to become ATP?

energy input is required to convert AMP to ADP, and the second phosphate is attached by a high-energy bond. Even more energy is required to add a third phosphate and create the high-energy compound **adenosine triphosphate (ATP)** (Figure 2–26).

The conversion of ADP to ATP is the most important method of storing energy in our cells. The breakdown of ATP to ADP is the most important method of releasing energy. The relationships involved in this energy transfer can be diagrammed as

The hydrolytic breakdown of ATP to ADP requires an enzyme known as **adenosine triphosphatase (ATPase)**, as well as a molecule of water. Throughout life, cells continuously generate ATP from ADP and then use the energy provided by the

breakdown of ATP to perform vital functions, such as the synthesis of proteins or the contraction of muscles.

ATP is our most abundant high-energy compound, but there are others. They are typically other nucleotides that have undergone phosphorylation. For example, *guanosine triphosphate* (GTP) is a nucleotide-based high-energy compound that transfers energy in specific enzymatic reactions.

Table 2–7 summarizes the inorganic and organic compounds covered in this chapter.

- 29. What molecule is produced by the phosphorylation of ADP?

See the blue Answers tab at the back of the book.

Table 2–7 Classes of Inorganic and Organic Compounds

Class	Building Blocks (Elements and/or Monomers)	Sources	Functions
INORGANIC			
Water	Hydrogen and oxygen atoms	Absorbed from the diet or generated by metabolism	Solvent; transport medium for dissolved materials and heat; cooling through evaporation; medium for chemical reactions; reactant in hydrolysis
Acids, bases, salts	H ⁺ , OH ⁻ , various anions and cations	Obtained from the diet or generated by metabolism	Structural components; buffers; sources of ions
Dissolved gases	O, C, N, and other atoms	Atmosphere, metabolism	O ₂ : required for cellular metabolism CO ₂ : generated by cells as a waste product NO: chemical messenger in cardiovascular, nervous, and lymphatic systems
ORGANIC			
Carbohydrates	C, H, O, in some cases N; CHO in a 1:2:1 ratio Monosaccharide monomers	Obtained from the diet or manufactured in the body	Energy source; some structural role when attached to lipids or proteins; energy storage
Lipids	C, H, O, in some cases N or P; CHO not in 1:2:1 ratio Fatty acids and glycerol monomers	Obtained from the diet or manufactured in the body	Energy source; energy storage; insulation; structural components; chemical messengers; protection
Proteins	C, H, O, N, commonly S Amino acid monomers	20 common amino acids; about half can be manufactured in the body, others must be obtained from the diet	Catalysts for metabolic reactions; structural components; movement; transport; buffers; defense; control and coordination of activities
Nucleic acids	C, H, O, N, and P; nucleotides composed of phosphates, sugars, and nitrogenous bases Nucleotide monomers	Obtained from the diet or manufactured in the body	Storage and processing of genetic information
High-energy compounds	Nucleotides joined to phosphates by high-energy bonds	Synthesized by all cells	Storage or transfer of energy

2 Chapter Review

Study Outline

An Introduction to the Chemical Level of Organization

1. Chemicals combine to form complex structures.

2-1 Atoms are the basic particles of matter

2. Atoms are the smallest units of matter. They consist of **protons**, **neutrons**, and **electrons**. Protons and neutrons reside in the **nucleus** of an atom.
3. The number of protons in an atom is its **atomic number**. Each **element** includes all the atoms that have the same number of protons and thus the same atomic number.
4. Within an atom, an **electron cloud** surrounds the nucleus. (Figure 2-1)
5. The **mass number** of an atom is the total number of protons and neutrons in its nucleus. **Isotopes** are atoms of the same element whose nuclei contain different numbers of neutrons.
6. Electrons occupy an orderly series of **energy levels**, commonly illustrated as **electron shells**. The electrons in the outermost energy level, or **valence shell**, determine an element's chemical properties. (Figures 2-2, 2-3)

2-2 Chemical bonds are forces formed by interactions between atoms

7. Atoms can combine through chemical reactions that create **chemical bonds**. A **molecule** is any chemical structure consisting of atoms held together by covalent bonds. A **compound** is a chemical substance made up of atoms of two or more elements in a fixed proportion.
8. The rules of **chemical notation** are used to describe chemical compounds and reactions. (Spotlight Figure 2-4)
9. An **ionic bond** results from the attraction between **ions**, atoms that have gained or lost electrons. **Cations** are positively charged; **anions** are negatively charged. (Figure 2-5)
10. Atoms that share electrons to form a molecule are held together by **covalent bonds**. A sharing of one pair of electrons is a **single covalent bond**; a sharing of two pairs is a **double covalent bond**; and a sharing of three pairs is a **triple covalent bond**. A bond with equal sharing of electrons is a **nonpolar covalent bond**; a bond with unequal sharing of electrons is a **polar covalent bond**. (Figures 2-6, 2-7)
11. A **hydrogen bond** is a weak, but important, electrical attraction that can affect the shapes and properties of molecules. (Figure 2-8)
12. Matter can exist as a **solid**, a **liquid**, or a **gas**, depending on the nature of the interactions among the component atoms or molecules.
13. The **molecular weight** of a molecule or a compound is the sum of the atomic weights of its component atoms.

2-3 Decomposition, synthesis, and exchange reactions are important types of chemical reactions in physiology

14. A chemical reaction occurs when **reactants** are rearranged to form one or more **products**. Collectively, all the **chemical reactions** in the body constitute its **metabolism**. Through

metabolism, cells capture, store, and use energy to maintain homeostasis and to perform essential functions.

15. **Work** is the movement of an object or a change in the physical structure of matter. **Energy** is the capacity to perform work.
16. **Kinetic energy** is the energy of motion. **Potential energy** is stored energy that results from the position or structure of an object. Conversions from potential to kinetic energy (or vice versa) are not 100% efficient. Every such energy conversion releases **heat**.
17. A chemical reaction is classified as a **decomposition**, a **synthesis**, or an **exchange reaction**.
18. Cells gain energy to power their functions by **catabolism**, the breakdown of complex molecules. Much of this energy supports **anabolism**, the synthesis of new molecules.
19. All chemical reactions are theoretically reversible. At **equilibrium**, the rates of two opposite reactions are in balance.

2-4 Enzymes speed up reactions by lowering the energy needed to start them

20. **Activation energy** is the amount of energy required to start a reaction. **Enzymes** are **catalysts**—compounds that accelerate chemical reactions without themselves being permanently changed or consumed. Enzymes promote chemical reactions by lowering the activation energy needed. (Figure 2-9)
21. **Exergonic** reactions release energy. **Endergonic** reactions absorb energy.

2-5 Inorganic compounds lack carbon, and organic compounds contain carbon

22. **Nutrients** are the essential elements and molecules normally obtained from the diet. **Metabolites**, on the other hand, are molecules that can be synthesized or broken down by chemical reactions inside our bodies. Nutrients and metabolites can be broadly categorized as either **inorganic** or **organic compounds**.

2-6 Physiological systems depend on water

23. Water is the most important constituent of the body.
24. A **solution** is a uniform mixture of two or more substances. It consists of a medium, or **solvent**, in which atoms, ions, or molecules of another substance, or **solute**, are individually dispersed. In **aqueous solutions**, water is the solvent. (Figure 2-10)
25. Many inorganic substances, called **electrolytes**, undergo **dissociation**, or **ionization**, in water to form ions. Molecules that interact readily with water molecules are called **hydrophilic**. Those that do not are called **hydrophobic**. (Figure 2-10; Table 2-2)

2-7 Body fluid pH is vital for homeostasis

26. The **pH** of a solution indicates the concentration of hydrogen ions it contains. Solutions are classified as **neutral**, **acidic**, or **basic** (*alkaline*) based on pH. (Figure 2-11)

2-8 Acids, bases, and salts have important physiological roles

- 2 27. An **acid** releases hydrogen ions. A **base** removes hydrogen ions from a solution. *Strong acids* and *strong bases* ionize completely. In the case of *weak acids* and *weak bases*, only some of the molecules ionize.
28. A **salt** is an electrolyte whose cation is not a hydrogen ion (H^+) and whose anion is not a hydroxide ion (OH^-).
29. **Buffers** remove or replace hydrogen ions in solution. Buffers and *buffer systems* in body fluids maintain the pH within normal limits.

2-9 Living things contain organic compounds made up of monomers, polymers, and functional groups

30. Carbon and hydrogen are the main constituents of **organic compounds**, which generally contain oxygen as well. Identical **monomers** join through *dehydration synthesis* reactions and form long complex chains called **polymers**. Organic polymers include carbohydrates, lipids, proteins, and nucleic acids.
31. The properties of the different classes of organic monomers and polymers are a result of the presence of *functional groups* of atoms. (Table 2-3)

2-10 Carbohydrates contain carbon, hydrogen, and oxygen in a 1:2:1 ratio

32. **Carbohydrates** are most important as an energy source for metabolic processes. The three major types of carbohydrates are **monosaccharides** (*simple sugars*), **disaccharides**, and **polysaccharides**. Disaccharides and polysaccharides form from monosaccharide monomers by **dehydration synthesis**. (Figures 2-12 to 2-14; Table 2-4)

2-11 Lipids often contain a carbon-to-hydrogen ratio of 1:2

33. **Lipids** include *fats*, *oils*, and *waxes*. Most are insoluble in water. The five important classes of lipids are **fatty acids**, **eicosanoids**, **glycerides**, **steroids**, and **phospholipids** and **glycolipids**. (Figures 2-15 to 2-19; Table 2-5)
34. **Triglycerides** (*neutral fats*) consist of three fatty acid molecules attached by dehydration synthesis to a molecule of **glycerol**. **Diglycerides** consist of two fatty acids and glycerol. **Monoglycerides** consist of one fatty acid plus glycerol. Fatty acids and glycerol are lipid monomers. (Figure 2-17)
35. Steroids (1) are components of plasma membranes, (2) include sex hormones and hormones regulating metabolic activities, and (3) are important in lipid digestion. (Figure 2-18)
36. **Phospholipids** and **glycolipids** are structural lipids that are components of *micelles* and plasma membranes. (Figure 2-19)

2-12 Proteins contain carbon, hydrogen, oxygen, and nitrogen and are formed from amino acids

37. **Proteins** perform a variety of essential functions in the body. Seven important types of proteins are *structural proteins*, *contractile proteins*, *transport proteins*, *buffering proteins*, *enzymes*, *hormones*, and *antibodies*.
38. Proteins are organic polymers made up of chains of **amino acids**. Each amino acid monomer consists of an *amino group*, a *carboxyl group*, a *hydrogen atom*, and an *R group* (*side chain*) attached to a central carbon atom. A **polypeptide** is a linear sequence of amino acids held together by **peptide bonds**; **proteins** are polypeptides containing over 100 amino acids. (Figures 2-20, 2-21)
39. The four levels of protein structure are **primary structure** (amino acid sequence), **secondary structure** (amino acid interactions, such as hydrogen bonds), **tertiary structure** (complex folding, disulfide bonds, and interaction with water molecules), and **quaternary structure** (formation of protein complexes from individual subunits). **Globular proteins**, such as *myoglobin* and *hemoglobin*, are generally rounded and water soluble. **Fibrous proteins**, such as *collagen* and *keratin*, are elongated, tough, durable, and generally insoluble. (Figure 2-22)
40. The reactants in an enzymatic reaction, called **substrates**, interact to yield a product by binding to the enzyme's **active site**. **Cofactors** are ions or molecules that must bind to the enzyme before the substrates can bind. **Coenzymes** are organic cofactors commonly derived from *vitamins*. (Figure 2-23)
41. The shape of a protein determines its functional characteristics. Each protein works best at an optimal combination of temperature and pH and will undergo temporary or permanent **denaturation**, or change in shape, at temperatures or pH values outside the normal range.

2-13 DNA and RNA are nucleic acids

42. **Nucleic acids** store and process information at the molecular level. The two kinds of nucleic acids are **deoxyribonucleic acid (DNA)** and **ribonucleic acid (RNA)**. (Figures 2-24, 2-25; Table 2-6)
43. Nucleic acids are organic polymers made up of chains of **nucleotides**. Each nucleotide contains a sugar, a phosphate group, and a **nitrogenous base**. The sugar is *ribose* in RNA and *deoxyribose* in DNA. DNA is a two-stranded double helix containing the nitrogenous bases **adenine**, **guanine**, **cytosine**, and **thymine**. RNA consists of a single strand and contains **uracil** instead of thymine.

2-14 ATP is a high-energy compound used by cells

44. Cells store energy in the *high-energy bonds* of **high-energy compounds**. The most important high-energy compound is **ATP (adenosine triphosphate)**. Cells make ATP by adding a phosphate group to **ADP (adenosine diphosphate)** through **phosphorylation**. When ATP is broken down to ADP and phosphate, energy is released. Cells can use this energy to power essential activities. (Figure 2-26; Table 2-7)

Review Questions

See the blue Answers tab at the back of the book.

LEVEL 1 Reviewing Facts and Terms

1. An oxygen atom has 8 protons. **(a)** Sketch in the arrangement of electrons around the nucleus of the oxygen atom in the following diagram. **(b)** How many more electrons will it take to fill the outermost energy level?

Oxygen atom

2. What is the following type of synthesis reaction called?

$$AH + BOH \longrightarrow AB + H_2O$$
3. The mass of an atom is determined primarily by the number of **(a)** protons, **(b)** neutrons, **(c)** electrons, **(d)** protons and neutrons.
4. Tritium is one of the three isotopes of a hydrogen atom. A tritium nucleus contains **(a)** 1 proton and 1 neutron, **(b)** 1 proton and 0 neutrons, **(c)** 0 protons and 1 neutron, **(d)** 1 proton and 2 neutrons.
5. The number of protons in the nucleus of an atom determines its **(a)** atomic number, **(b)** possibility of radiation emission, **(c)** chemical properties, **(d)** molecular weight.
6. In the human body, the element that constitutes the highest percentage of the total body weight is **(a)** hydrogen, **(b)** carbon, **(c)** oxygen, **(d)** calcium, **(e)** nitrogen.
7. Sucrose is a molecule present in many popular junk foods. It is a **(a)** disaccharide, **(b)** monosaccharide, **(c)** dipeptide, **(d)** polysaccharide, **(e)** polypeptide.
8. Decomposition reactions of complex molecules in the cells and tissues of the human body are collectively referred to as **(a)** metabolism, **(b)** catabolism, **(c)** anabolism, **(d)** equilibrium.
9. Which of the following examples of chemical reactions is a hydrolysis reaction?
(a) $AB + CD \longrightarrow AD + CB$
(b) $AB + H_2O \longrightarrow AH + BOH$
(c) $AH + BOH \longrightarrow AB + H_2O$
(d) $AB \longrightarrow A + B$
10. An amino group is a functional group that can **(a)** act as an acid, **(b)** act as a base, **(c)** store energy, **(d)** increase molecule solubility.
11. In our stomach, gastric juice helps to digest nutrients. It is **(a)** weakly acidic, **(b)** weakly basic, **(c)** strongly acidic, **(d)** strongly basic.
12. The formation of NaCl requires a(n) _____ bond; the formation of N₂ requires a(n) _____ bond. **(a)** ionic; double covalent, **(b)** covalent; ionic, **(c)** ionic; triple covalent, **(d)** double ionic; covalent.
13. Enzymes, which speed up chemical reactions in the human body, are _____. **(a)** polysaccharides, **(b)** lipids, **(c)** pyrimidines, **(d)** purines, **(e)** proteins.
14. What is the typical function of a DNA molecule? **(a)** to encode information to build proteins, **(b)** to store energy, **(c)** to build up plasma membrane, **(d)** to control chemical reactions, **(e)** to act as antibodies.

15. A characteristic of DNA is that it has **(a)** paired strands coiled in a double helix, **(b)** 50,000 or fewer nucleotides, **(c)** uracil, **(d)** ribose.
16. What are the three subatomic particles in atoms?
17. What are the three structural classes of carbohydrates found in the body?
18. List three important functions of triglycerides (neutral fats) in the body.
19. List seven major functions performed by proteins.
20. **(a)** What three basic components make up a nucleotide of DNA? **(b)** What three basic components make up a nucleotide of RNA?
21. What are the most important methods of storing and releasing energy in our cells?

LEVEL 2 Reviewing Concepts

22. If a polypeptide contains 10 peptide bonds, how many amino acids does it contain? **(a)** 9, **(b)** 10, **(c)** 11, **(d)** 12.
23. Aside from a phosphate group, what else is essential for building up lecithin? **(a)** ribose, **(b)** iron, **(c)** glycerol, **(d)** uracil, **(e)** an amino group.
24. Explain why strongly radioactive isotopes are dangerous.
25. What is a buffer? What is the significance of buffers in biochemical reactions?
26. What is the difference between potential energy and kinetic energy?
27. In an endergonic reaction, **(a)** the amount of energy released is greater than that of the activation energy, **(b)** enzymes are always needed, **(c)** large molecules are broken down into smaller ones, **(d)** the reaction as a whole absorbs energy, **(e)** heat is generated to maintain body temperature.
28. The hydrogen bonding that occurs in water is responsible for all the following *except* **(a)** the high boiling point of water, **(b)** the low freezing point of water, **(c)** the ability of water to dissolve nonpolar substances, **(d)** the ability of water to dissolve inorganic salts, **(e)** the surface tension of water.
29. A sample that contains an organic molecule has the following constituents: carbon, hydrogen, oxygen, nitrogen, and phosphorus. Is the molecule more likely to be a carbohydrate, a lipid, a protein, or a nucleic acid?

LEVEL 3 Critical Thinking and Clinical Applications

30. An atom of the element magnesium has 12 protons and 12 neutrons. Determine the following information about magnesium: **(a)** number of electrons, **(b)** atomic number, **(c)** atomic weight, **(d)** number of electrons in each energy level.
31. A certain reaction pathway consists of four steps. How would decreasing the amount of enzyme that catalyzes the second step affect the amount of product produced at the end of the pathway?
32. Yang has decided to change his lifestyle and become a vegetarian. His friends warn him that maybe a diet lacking in cholesterol might cause a shortage in the amount of cholesterol his body requires. A dietitian tells Yang why this will not be the case.

CLINICAL CASE Wrap-Up What Is Wrong with My Baby?

2

Baby Sean has *cystic fibrosis* (CF), a life-threatening genetic disease. He inherited a defective gene from each parent. This faulty gene adversely affects the transport of salt—sodium chloride (NaCl)—into and out of cells. As a result, thick, sticky secretions are produced in both the digestive and respiratory systems.

In someone with CF, the digestive juices produced are so thick they clog in the pancreas and cannot get into the small intestine. Digestive juices contain enzymes that break down carbohydrates, lipids, and proteins in food so that they can be absorbed and used by cells. Without these enzymes, Sean's food passes right through him without being digested, leading to weight loss and fatty stools. In addition, the abnormal secretions clog the lungs, making Sean short of breath, wheezy, and susceptible to repeated lung infections. Finally, CF makes his skin taste very salty because of salt being lost in the sweat.

The diagnosis of cystic fibrosis is made with a sweat test. A sweat-producing chemical is applied to an area of Sean's skin, and the sweat is collected and tested for chloride concentration.

Sean's treatment starts immediately. His parents give him digestive enzymes before each feeding so that he can absorb nutrients. Sean's parents learn chest physical therapy: For 20–60 minutes, twice per day, they percuss (clap force-

fully with a cupped hand) and vibrate (shake with an open hand) his chest to loosen the thick mucus so he can cough it up and out. Soon Sean gains weight and begins to thrive, but this therapy will be lifelong.

1. What undigested substances would have made Sean's stools greasy and foamy?
2. Why are digestive enzymes necessary for life?

See the blue Answers tab at the back of the book.

Related Clinical Terms

artificial sweetener: Organic molecules that can stimulate taste buds and provide a sweet taste to foods without adding substantial amounts of calories to the diet.

heavy metal: The term used for a group of elements with relatively high atomic weights, atomic numbers, or densities. Some

heavy metals—cobalt, copper, iron, manganese, molybdenum, vanadium, strontium, and zinc—are essential to health in trace amounts. Others are nonessential and can be harmful to health in excessive amounts. These include cadmium, antimony, chromium, mercury, lead, and arsenic.

3

The Cellular Level of Organization

Learning Outcomes

These Learning Outcomes correspond by number to this chapter's sections and indicate what you should be able to do after completing the chapter.

- 3-1 ■ List the functions of the plasma membrane and the structural features that enable it to perform those functions.
- 3-2 ■ Describe the organelles of a typical cell and indicate the specific functions of each.
- 3-3 ■ Explain the functions of the cell nucleus and discuss the nature and importance of the genetic code.
- 3-4 ■ Summarize the role of DNA in protein synthesis, cell structure, and cell function.
- 3-5 ■ Describe the processes of cellular diffusion and osmosis and explain their role in physiological systems.
- 3-6 ■ Describe carrier-mediated transport and vesicular transport mechanisms used by cells to facilitate the absorption or removal of specific substances.
- 3-7 ■ Explain the origin and significance of the cell membrane potential.
- 3-8 ■ Describe the stages of the cell life cycle, including interphase, mitosis, and cytokinesis, and explain their significance.
- 3-9 ■ Discuss the regulation of the cell life cycle.
- 3-10 ■ Discuss the relationship between cell division and cancer.
- 3-11 ■ Define cellular differentiation and explain its importance.

CLINICAL CASE Mohan Gets the Runs

3

Mohan, a 37-year-old geologist, suddenly began to feel unwell soon after returning home to Mumbai after a work trip abroad. At first, he just felt nauseated, but this soon worsened, and he began to vomit clear fluid and have profuse, watery diarrhea.

On the first day, Mohan attempted to treat himself by taking aspirin and drinking fluids, but his condition continued to deteriorate, and he became increasingly thirsty and could not retain any food. Ashika, his wife, was concerned and decided to take him to their family doctor. On examining Mohan, the doctor noted that he had a dry mouth, a loss of skin elasticity, and low blood pressure. The doctor asked Mohan if he had been traveling recently and Mohan

told him that he had just returned from a work trip to a remote location.

“Did you drink the local water when you were there?” the doctor asked.

“Yes, I did.” replied Mohan.

The doctor nodded knowingly and proceeded to order various laboratory tests to further investigate Mohan’s condition, including a request to test a stool sample. The sample indicated a positive result for the presence of *Vibrio cholerae*.

Mohan was thirsty and had low blood pressure, inelastic skin, and a dry mouth. **What**

do these signs tell you about Mohan’s

general condition? To find out, turn to the Clinical Case Wrap-Up at the end of the chapter.

An Introduction to Cells

This chapter introduces how combinations of chemicals form *cells*, the smallest living units in the human body. The chemical events that sustain life, which occur mostly inside cells, are also presented.

Much anatomy and physiology cannot be seen with the unaided eye because cells are very small. The unaided human eye can see objects only about 0.1 mm in diameter. A typical cell is much smaller than that. As a result, no one could examine the structure of a cell until effective microscopes were invented about 400 years ago and the field of *microscopy* (investigating objects using a microscope) was born. Microscopes have evolved from the compound light microscope, which magnifies objects up to 1000 times, to the scanning electron microscope, which can magnify an object from 10 to 500,000 times!

Over time, the work of scientists in this area led to the development of the *cell theory*. We can summarize its basic concepts as follows:

- Cells are the building blocks of all organisms.
- All cells come from the division of preexisting cells.
- Cells are the smallest units that carry out life’s essential physiological functions.
- Each cell maintains homeostasis at the cellular level.
Homeostasis at the tissue, organ, organ system, and organism levels results from the combined feedback of many cells.

The human body contains trillions of cells. All our activities—from running to thinking—result from the coordinated actions of millions or even billions of cells. Many insights into human physiology arose from studies of individual cell function. What we have learned over the years has given us a new understanding of cellular physiology and homeostatic control mechanisms. Today, the study of cellular structure and function,

or **cytology**, is part of the broader discipline of **cell biology**, which integrates aspects of biology, chemistry, and physics.

The human body contains two general classes of cells: sex cells and somatic cells. **Sex cells** form either *sperm* or *oocytes* (ō-ō-sītz), the immature ova (“eggs”). The fusion of a sperm and an oocyte at fertilization is the first step in the development of a new individual. **Somatic cells**, or body cells, include all other cells. In this chapter, we focus on somatic cells. We discuss sex cells in Chapters 28 and 29.

In the rest of this chapter, we describe the structure of a typical somatic cell, consider some of the ways in which cells interact with their environment, and discuss how somatic cells reproduce. Keep in mind that the “typical” somatic cell is like the “average” person: Any description masks many individual variations. **Spotlight Figure 3–1** summarizes the anatomy of a typical cell.

3-1 The plasma membrane separates the cell from its surrounding environment and performs various functions

Learning Outcome List the functions of the plasma membrane and the structural features that enable it to perform those functions.

When viewing an animal cell through a microscope, the first structure encountered is its outer boundary, called the **plasma membrane**, or **cell membrane**. Membranes are neither rigid nor uniform in structure. At each location, the inner and outer surfaces of the plasma membrane may differ in important ways. For example, some enzymes are found only on the inner surface of the membrane, and some receptor molecules are found only on the outer surface. In general, plasma membranes have these functions:

- **Physical Isolation.** The plasma membrane is a physical barrier that separates the inside of the cell, or *cytoplasm*,

from the surrounding extracellular fluid. For example, the plasma membrane keeps enzymes and structural proteins inside the cell. Conditions inside and outside the cell are very different, and those differences must be maintained to preserve homeostasis.

- **Regulation of Exchange with the Environment.** The plasma membrane acts as a gatekeeper. It controls the entry of ions and nutrients, the elimination of wastes, and the release of secretions.
- **Sensitivity to the Environment.** The plasma membrane is the first part of the cell affected by changes in the composition, concentration, or pH of the extracellular fluid. It also contains a variety of special structural molecules known as *receptors* that allow the cell to recognize and respond to specific molecules in its environment. For instance, the plasma membrane may receive chemical signals from other cells. The binding of just one molecule to a receptor may trigger the activation or deactivation of enzymes that affect many cellular activities.
- **Structural Support.** Specialized connections between plasma membranes, or between membranes and extracellular materials, give tissues stability. For example, the cells at the surface of the skin are tightly bound together, while those in the deepest layers are attached to extracellular protein fibers in underlying tissues.

The plasma membrane is extremely thin, ranging from 6 to 10 nm in thickness. The membrane contains lipids, proteins, and carbohydrates.

Membrane Lipids

Lipids form most of the surface area of the plasma membrane, but they make up only about 42% of its weight. The plasma membrane is called a **phospholipid bilayer** because the phospholipid molecules in it form two layers (**Figure 3-2**).

Recall from Chapter 2 that a phospholipid has both a hydrophilic end (the phosphate portion) and a hydrophobic end (the lipid portion). In each half of the bilayer, the phospholipids lie with their hydrophilic heads at the membrane surface and their hydrophobic tails on the inside. In this arrangement, the hydrophilic (“water-loving”) heads of the two layers are in contact with the watery environments on both sides of the membrane—the extracellular fluid outside the cell and the intracellular fluid, or *cytosol*, inside the cell. (The cytosol is the fluid component of the cytoplasm.) The hydrophobic (“water-fearing”) tails form the interior of the membrane.

The lipid bilayer also contains cholesterol and other steroids, small quantities of other lipids, proteins, and glycolipids. Cholesterol is an important component of plasma membranes, with almost one cholesterol molecule for each phospholipid

molecule. Cholesterol “stiffens” the plasma membrane, making it less fluid and less permeable.

Note the similarities in lipid organization between the plasma membrane and a micelle (look back at **Figure 2-19c**). Ions and water-soluble compounds cannot enter a micelle because the lipid tails of the phospholipid molecules are hydrophobic and will not associate with water molecules. For the same reason, such substances cannot cross the lipid portion of the plasma membrane. In this way, the hydrophobic center of the membrane isolates the cytoplasm from the surrounding fluid environment.

Membrane Proteins

Proteins, which are much denser than lipids, account for about 55% of the weight of a plasma membrane. There are two general structural classes of membrane proteins based on their location, integral and peripheral (**Figure 3-2**). **Integral proteins** are part of the plasma membrane structure and cannot be easily separated from it without damaging or destroying the membrane. Most integral proteins span the width of the membrane one or more times and are known as *transmembrane proteins*. These proteins contain hydrophobic portions embedded within the hydrophobic lipid bilayer, with their hydrophilic portions extended into the extracellular environment and cytosol. **Peripheral proteins** are bound to the inner or outer surface of the membrane and are easily separated from it. Integral proteins greatly outnumber peripheral proteins.

Various types of membrane proteins carry out specialized functions. Here are some examples of important types of membrane proteins:

- **Anchoring Proteins.** **Anchoring proteins** attach the plasma membrane to other structures and stabilize its position. Inside the cell, membrane proteins are bound to the *cytoskeleton*, a network of supporting filaments in the cytoplasm. Outer membrane proteins may attach the cell to extracellular protein fibers or to another cell.
- **Recognition Proteins (Identifiers).** The cells of the immune system recognize other cells as normal or abnormal based on the presence or absence of characteristic **recognition proteins**. Many important recognition proteins are glycoproteins. (We discuss one group, the MHC proteins involved in the immune response, in Chapter 22.)
- **Enzymes.** Enzymes in plasma membranes may be integral or peripheral proteins. They catalyze reactions in the extracellular fluid or in the cytosol, depending on their location. For example, dipeptides are broken down into amino acids by enzymes on the extracellular membrane surfaces of cells that line the intestinal tract.

In our model cell, a plasma membrane separates the cell contents, called the cytoplasm, from its surroundings. The cytoplasm can be subdivided into the cytosol, a fluid, and intracellular structures collectively known as organelles (or-ga-NELZ). Organelles are structures suspended within the cytosol that have specific functions within the cell. They can be subdivided into membranous and nonmembranous organelles. Cells are surrounded by a watery substance called the **extracellular fluid**. The extracellular fluid in most tissues is called **interstitial** (in-ter-STISH-ul) **fluid**.

Nonmembranous Organelles

Microvilli

Microvilli are extensions of the plasma membrane containing microfilaments.

Function

Increase surface area to help absorb extracellular materials

Centrosome and Centrioles

Cytoplasm containing two centrioles at right angles; each centriole is composed of 9 microtubule triplets in a 9 + 0 array

Functions

Essential for movement of chromosomes during cell division; organization of microtubules in cytoskeleton

Cytoskeleton

Proteins organized in fine filaments or slender tubes

Functions

Strength and support; movement of cellular structures and materials

Cilia

Cilia are long extensions of the plasma membrane containing microtubules. There are two types: primary and motile.

Functions

A primary cilium acts as a sensor. Motile cilia move materials over cell surfaces

Proteasomes

Hollow cylinders of proteolytic enzymes with regulatory proteins at their ends

Functions

Breakdown and recycling of damaged or abnormal intracellular proteins

Ribosomes

RNA + proteins; fixed ribosomes bind to rough endoplasmic reticulum; free ribosomes are scattered in cytoplasm

Function

Protein synthesis

Plasma Membrane

Lipid bilayer containing phospholipids, steroids, proteins, and carbohydrates

Cytosol (distributes materials by diffusion)

Functions

Isolation; protection; sensitivity; support; controls entry and exit of materials

Membranous Organelles

Golgi apparatus

Stacks of flattened membranes (cisternae) containing chambers

Functions

Storage, alteration, and packaging of secretory products and lysosomal enzymes

Endoplasmic reticulum (ER)

Network of membranous channels extending throughout the cytoplasm

Functions

Synthesizes secretory products; intracellular storage and transport; detoxifies drugs or toxins

Rough ER has ribosomes, and it modifies and packages newly synthesized proteins

Smooth ER does not have ribosomes and synthesizes lipids and carbohydrates

Peroxisomes

Vesicles containing degradative enzymes

Functions

Catabolizes fats and other organic compounds; neutralizes toxic compounds generated in the process

Mitochondria

Double membrane, with inner membrane folds (cristae) enclosing important metabolic enzymes

Function

Produce 95% of the ATP required by the cell

Lysosomes

Vesicles containing digestive enzymes

Function

Intracellular removal of damaged organelles or pathogens

Nucleus

Nucleoplasm containing nucleotides, enzymes, nucleoproteins, and chromatin; surrounded by a double membrane, the nuclear envelope

Functions

Controls metabolism; stores and processes genetic information; controls protein synthesis

- **Carrier Proteins.** **Carrier proteins** bind solutes and transport them across the plasma membrane. Carrier proteins may require ATP as an energy source. For example, virtually all cells have carrier proteins that bring glucose into the cytoplasm without expending ATP. Yet these cells must use ATP to transport ions such as sodium (Na^+) and calcium (Ca^{2+}) out of the cytoplasm and across the plasma membrane.
- **Channels.** Some integral proteins contain a **channel**, or central pore, that forms a passageway completely through the plasma membrane. Such channels permit water and small solutes to move across the plasma membrane. Ions do not dissolve in lipids, so they cannot cross the phospholipid bilayer. For this reason, ions and other small

water-soluble substances can cross the membrane only by passing through channels. Most of the communication between the interior and exterior of the cell occurs through these channels. Some of the channels are called **gated channels** because they can open or close to regulate the passage of substances. Channels account for about 0.2% of the total surface area of the plasma membrane, but they are extremely important in physiological processes such as muscle contraction and nerve impulse transmission, as we discuss in Chapters 10 and 12.

Some integral and peripheral proteins are always confined to specific areas of the plasma membrane. These areas, called *rafts*, mark the location of anchoring proteins and some kinds of receptor proteins. Because membrane phospholipids are fluid at body temperature, many other integral proteins drift across the surface of the membrane like ice cubes in a bowl of punch. In addition, the composition of the entire plasma membrane can change over time as large areas of the membrane surface are removed and recycled in the ongoing process of metabolic turnover. A table listing the turnover times of the organic components of representative cells is found in Appendix C.

Membrane Carbohydrates

Carbohydrates account for about 3% of the weight of a plasma membrane. The carbohydrates in the plasma membrane are parts of complex molecules such as *proteoglycans*, *glycoproteins*, and *glycolipids*. The carbohydrate portions of these large molecules extend beyond the outer surface of the membrane, forming a layer known as the **glycocalyx** (glī-kō-KĀ-lik; *calyx*, cup).

The glycocalyx has a variety of important functions, including the following:

- **Lubrication and Protection.** The glycoproteins and glycolipids form a viscous (thick and sticky) layer that lubricates and protects the plasma membrane.
- **Anchoring and Locomotion.** Because its components are sticky, the glycocalyx can help anchor the cell in place. It also takes part in the movement of specialized cells.
- **Specificity in Binding.** Glycoproteins and glycolipids can function as receptors, binding specific extracellular compounds. Such binding can change the properties of the cell surface and indirectly affect the cell's functions.
- **Recognition.** Cells involved with the immune response recognize glycoproteins and glycolipids as normal or abnormal. The characteristics of the glycocalyx are genetically determined. The body's immune system recognizes its own membrane glycoproteins and glycolipids as "self" rather than as "foreign." This recognition system keeps the immune system from attacking its cells and allows it to recognize and destroy invading pathogens (disease-causing agents).

The plasma membrane forms a barrier between the cytosol and the extracellular fluid. If the cell is to survive, dissolved substances and larger compounds must be able to cross this barrier. Nutrients must be able to enter the cell, and metabolic wastes must be able to leave. The structure of the plasma membrane is ideally suited to this need for selective transport. We discuss selective transport and other membrane functions further, after we have completed our overview of cellular anatomy.

Checkpoint

1. List the general functions of the plasma membrane.
2. Identify the components of the plasma membrane that allow it to carry out its functions.
3. Which component of the plasma membrane is primarily responsible for the membrane's ability to form a physical barrier between the cell's internal and external environments?
4. Which type of integral protein allows water, ions, and small water-soluble solutes to pass through the plasma membrane?

See the blue Answers tab at the back of the book.

3-2 Organelles within the cytoplasm perform particular functions

Learning Outcome Describe the organelles of a typical cell and indicate the specific functions of each.

Cytoplasm is a general term for the material between the plasma membrane and the membrane that surrounds the nucleus. The cytoplasm has three major subdivisions: cytosol, organelles, and inclusions. **Cytosol** is also known as *intracellular fluid*. It is a mixture of water and various dissolved and insoluble materials in which the organelles and inclusions are suspended. Cytosol is a colloid with a consistency that varies between that of thin maple syrup and almost-set gelatin. Cytosol contains many more proteins than does extracellular fluid, the watery substance that surrounds cells. These proteins are so important to the cell that they make up about 30% of a typical cell's weight.

Organelles ("little organs") are the internal structures of cells with tasks that keep a cell alive and functioning normally. Each organelle has specific functions related to cell structure, growth, maintenance, and metabolism. We divide cellular organelles into two broad categories, nonmembranous and membranous. **Nonmembranous organelles** are not completely enclosed by membranes, and all their components are in direct contact with the cytosol. **Membranous organelles** are isolated from the cytosol by phospholipid membranes, just as the plasma membrane isolates the cytosol from the extracellular fluid. The *nucleus* is also surrounded by a membranous

envelope—and is, strictly speaking, a membranous organelle. It has so many vital functions that we consider it in a separate section.

Inclusions are masses of insoluble materials. Some inclusions are stored nutrients, such as glycogen granules in liver or skeletal muscle cells and lipid droplets in fat cells. Others are pigment granules, such as the brown skin pigment *melanin* found in hair and skin cells.

3

The Cytosol

Cytosol is different from extracellular fluid. Some important differences between cytosol and extracellular fluid are as follows:

- **Sodium and Potassium Ion Concentrations.** The concentration of potassium ions (K^+) is higher in the cytosol than in the extracellular fluid, whereas the concentration of sodium ions (Na^+) is lower in the cytosol than in the extracellular fluid.
- **Suspended Protein Concentrations.** The cytosol contains a much higher concentration of suspended proteins than does extracellular fluid. Many of the proteins are enzymes that regulate metabolic operations. Others are associated with the various organelles. The consistency of the cytosol is determined in large part by the enzymes and cytoskeletal proteins.
- **Nutrient Concentrations.** The cytosol usually contains smaller quantities of carbohydrates and lipids, and smaller reserves of amino acids than does the extracellular fluid. The extracellular fluid is a transport substance only, and no materials are stored there. The carbohydrates in the cytosol are broken down to provide energy. When carbohydrates are unavailable, lipids, in particular triglycerides, are used as a source of energy. The amino acids are primarily used to manufacture proteins.

Nonmembranous Organelles

Nonmembranous organelles do not have a definite boundary. The cell's nonmembranous organelles include the *cytoskeleton*, *centrosome* with *centrioles*, *ribosomes*, and *proteasomes*. Some cells also have cellular extensions, which include *microvilli*, *cilia*, and *flagella*.

The Cytoskeleton

The **cytoskeleton** serves as the cell's skeleton. It is an internal protein framework that gives the cytosol strength and flexibility. The cytoskeleton of all cells is made of *microfilaments*, *intermediate filaments*, and *microtubules* (Figure 3–3). Muscle cells contain these cytoskeletal elements plus *thick filaments*. The filaments and microtubules of the cytoskeleton form a dynamic network whose continual reorganization affects cell shape and

function. This network provides support for organelles and keeps them in their proper positions. Interactions between cytoskeletal components are also important in moving organelles and in changing the cell shape.

We consider a few of the many functions of the cytoskeleton in this section. In addition to the functions we describe here, the cytoskeleton plays a role in the metabolic organization of the cell. It determines where in the cytoplasm key enzymatic reactions take place and where specific proteins are synthesized. For example, many enzymes (especially those involved with metabolism and energy production), ribosomes, and RNA molecules responsible for protein synthesis are attached to the microfilaments and microtubules of the cytoskeleton. The varied metabolic functions of the cytoskeleton are subjects of intensive research.

Microfilaments. The smallest cytoskeletal structures are the rod-shaped **microfilaments**. These protein strands are generally about 5 nm in diameter. Typical microfilaments are made of the protein **actin**. In skeletal muscle cells, the thin actin filaments interact with other protein strands of thick *myosin* filaments to cause contraction. In cells that form a layer or lining, such as the lining of the intestinal tract, actin filaments also form a layer, called the *terminal web*, just inside the plasma membrane at the exposed surface of the cell (Figure 3–3a).

Microfilaments have the following major functions:

- Microfilaments anchor the cytoskeleton to integral proteins of the plasma membrane. They give the cell additional mechanical strength and attach the plasma membrane to the enclosed cytoplasm.
- Microfilaments, interacting with other proteins, determine the consistency of the cytosol. Where microfilaments form a dense, flexible network, the cytosol has a gelatinous consistency. Where they are widely dispersed, the cytosol is more fluid.

Intermediate Filaments. The protein composition of **intermediate filaments** varies among cell types. These filaments range from 9 to 11 nm in diameter. They are so named because they are intermediate in size between microfilaments and microtubules. Intermediate filaments, which are insoluble in the watery substance, are the most durable of the cytoskeletal elements.

Intermediate filaments (1) *strengthen the cell* and help maintain its shape, (2) *stabilize the positions of organelles*, and (3) *stabilize the position of the cell with respect to surrounding cells* through specialized attachments to the plasma membrane. Many cells contain specialized intermediate filaments with unique functions. For example, the keratin fibers in superficial layers of the skin are intermediate filaments that make these layers strong and stretch resistant.

Microtubules. Most cells contain **microtubules**, hollow tubes built from the globular protein **tubulin**. Microtubules are the

Figure 3-3 The Cytoskeleton.

What are the three different components that make up the cytoskeleton in all body cells?

largest components of the cytoskeleton, with diameters of about 25 nm. Microtubules extend outward into the periphery of the cell from a region near the nucleus called the *centrosome* (**Spotlight Figure 3-1**).

Each microtubule forms by the aggregation of tubulin molecules, growing out from its origin at the centrosome. The entire structure persists for a time and then disassembles into individual tubulin molecules again.

Microtubules have the following functions:

- Microtubules form the main portions of the cytoskeleton, giving the cell strength, maintaining its shape, and anchoring the position of major organelles.
- Microtubules change the shape of the cell and may assist in cell movement, through the assembly and disassembly of microtubules.
- Microtubules can act as a monorail system to move vesicles or other organelles within the cell. Proteins called **motor proteins** create the movement. These motor proteins bind to both the structure being moved and to a microtubule and then move along its length. The direction of movement depends on the specific motor protein involved. For example, the proteins *kinesin* and *dynein* ($\text{D}\bar{\text{I}}\text{-n}\bar{\text{e}}\text{n}$) carry materials in opposite directions on a microtubule: Kinesin moves toward one end, dynein toward the other. Regardless of the transport direction or the nature of the motor, the process requires ATP and is essential to normal cellular function.
- During cell division, microtubules distribute duplicated chromosomes containing DNA to opposite ends of the dividing cell by forming a network of microtubules called the *spindle apparatus*. We look at this process in more detail in Section 3-8.
- Microtubules form structural components of organelles, such as centrioles and cilia.

Microvilli

Many cells have small, finger-shaped projections of the plasma membrane on their exposed surfaces (**Figure 3-3b**). These nonmotile projections, called **microvilli** (singular, *microvillus*), greatly increase the surface area of the cell exposed to the extracellular environment. Accordingly, they cover cell surfaces that are actively absorbing materials, such as the cells lining the digestive tract. Microvilli have extensive connections with the cytoskeleton. A core of microfilaments stiffens each microvillus and anchors it to the cytoskeleton at the terminal web.

Centrosome and Centrioles

The **centrosome** is a region of cytoplasm located next to the nucleus in a cell. It is the *microtubule-organizing center* of animal cells and is a vital part of the cytoskeletal system. Microtubules of the cytoskeleton generally begin at the centrosome and radiate out through the cytoplasm. In all animal cells capable of undergoing cell division, the centrosome surrounds a pair of cylindrical structures called **centrioles**. The centrioles lie perpendicular to each other and are made of short microtubules. The microtubules form nine groups, three in each group.

Each of these nine “triplets” is connected to its nearest neighbors on each side. Because there are no central microtubules, this organization is called a $9 + 0$ array (**Figure 3-4a**).

During cell division, the centrioles aid the formation of the spindle apparatus needed for the movement of chromosomes. Mature red blood cells, skeletal muscle cells, cardiac muscle cells, and typical neurons have no centrioles, and as a result, these cells cannot divide. The centrioles also form the *basal bodies* found at the base of some cellular extensions.

Cilia and Flagella

Cilia (singular, *cilium*) are long, slender extensions of the plasma membrane. Two types of cilia are found in human cells, *nonmotile* and *motile*.

A single, nonmotile **primary cilium** is found on the cells of a wide variety of tissues in the body. Its structure is similar to the $9 + 0$ microtubule organization of a centriole. The primary cilium acts as a signal sensor, detecting environmental stimuli and coordinating activities such as embryonic development and homeostasis at the tissue level.

Multiple **motile cilia** are found on cells lining both the respiratory and reproductive tracts and at various other locations in the body. Motile cilia have an internal arrangement similar to that of centrioles. However, in cilia, nine *pairs* of microtubules (rather than triplets) surround a central pair (**Figure 3-4b**)—an organization known as a $9 + 2$ array. The microtubules are anchored to a compact **basal body** located just beneath the cell surface. The organization of microtubules in the basal body resembles the array of a centriole: nine triplets with no central pair.

Motile cilia are important because they “beat” rhythmically to move fluids or secretions across the cell surface (**Figure 3-4c**). A motile cilium is relatively stiff during the *power stroke* and flexible during the *return stroke*. For example, the ciliated cells along the trachea beat their cilia in synchronized waves to move sticky mucus and trapped dust particles toward the throat and away from delicate respiratory surfaces. If the cilia are damaged or immobilized by heavy smoking or a metabolic problem, this cleansing action is lost. When irritants are no longer removed, a chronic cough and respiratory infections develop. Ciliated cells also move oocytes along the uterine tubes and sperm from the testes into the reproductive tract. Defective primary cilia are responsible for a wide range of human disorders, collectively known as *ciliopathies*.

A **flagellum** (plural, *flagella*) is a whiplike extension of the plasma membrane. Flagella have the same $9 + 2$ microtubule organization as motile cilia, but they are much longer and beat in a wavelike motion. The only human cell with a flagellum is a sperm, and there is only one flagellum per cell. Sperm with multiple flagella are abnormal and cannot fertilize an oocyte.

Figure 3-4 Centrioles and Cilia.

a Centriole. A centriole consists of nine microtubule triplets (known as a 9 + 0 array). A pair of centrioles oriented at right angles to one another occupies the centrosome. This micrograph, produced by a transmission electron microscope, is called a TEM.

b Motile cilium. A motile cilium contains nine pairs of microtubules surrounding a central pair (9 + 2 array). The basal body to which it is anchored has a microtubule array similar to that of a centriole.

c Ciliary movement. Action of a single motile cilium. During the power stroke, the cilium is relatively stiff. During the return stroke, it bends and returns to its original position.

Ribosomes

Now let's turn to how proteins are produced within cells, using information provided by the DNA of the nucleus. **Ribosomes** are the organelles responsible for protein synthesis. The number of ribosomes in a particular cell varies with the type of cell and its demand for new proteins. For example, liver cells, which manufacture blood proteins, contain far more ribosomes than do fat cells, which primarily synthesize lipids.

Individual ribosomes are not visible with a light microscope. In an electron micrograph, they appear as dense granules approximately 25 nm in diameter. Each ribosome is about 60% RNA and 40% protein.

A functional ribosome consists of two subunits that are normally separate and distinct. One is called a **small ribosomal subunit** and the other a **large ribosomal subunit**.

These subunits contain special proteins and **ribosomal RNA (rRNA)**, one of the RNA types introduced in Chapter 2. Before protein synthesis can begin, a small and a large ribosomal subunit in the cytoplasm must join with a strand of *messenger RNA* (mRNA), another type of RNA. Protein synthesis then begins in the cytoplasm.

The two major types of functional ribosomes in cells are free ribosomes and fixed ribosomes. **Free ribosomes** are scattered throughout the cytoplasm. The proteins they manufacture directly enter the cytosol. Ribosomes synthesizing proteins with destinations other than the cytosol become temporarily bound, or fixed, to the *endoplasmic reticulum* (ER), a membranous organelle. Proteins manufactured by such fixed ribosomes enter the ER, where they are modified and packaged for use within the cell or are secreted from the cell. We look at

ribosomal structure and functions when we discuss the endoplasmic reticulum and protein synthesis in later sections.

Proteasomes

Proteasomes are organelles that contain an assortment of protein-digesting (proteolytic) enzymes, or *proteases*. They are smaller than free ribosomes and they remove proteins from the cytoplasm. Cytoplasmic enzymes attach chains of *ubiquitin*, a molecular “tag,” to proteins destined for recycling. Tagged proteins are quickly transported into a proteasome. Once inside, they are rapidly disassembled into amino acids and small peptides, which are released into the cytoplasm.

Proteasomes remove and recycle damaged or denatured proteins. They also break down abnormal proteins, such as those produced within cells infected by viruses. Proteasomes also play a key role in the immune response, as described in Chapter 22.

Before reading about membranous organelles in the next section, review **Spotlight Figure 3-1**, which highlights the characteristics of nonmembranous organelles.

Membranous Organelles

Membranous organelles include the *endoplasmic reticulum*, the *Golgi apparatus*, *lysosomes*, *peroxisomes*, and *mitochondria*.

The Endoplasmic Reticulum

The **endoplasmic reticulum** (en-dō-PLAZ-mik re-TIK-ū-lum), or **ER**, is a network of intracellular membranes continuous with the *nuclear envelope*, which surrounds the nucleus.

The name *endoplasmic reticulum* is very descriptive. *Endo-* means “within,” *plasm* refers to the cytoplasm, and a *reticulum* is a network. The ER has the following major functions:

- **Synthesis.** Specialized regions of the ER synthesize proteins, carbohydrates, and lipids.
- **Storage.** The ER can store synthesized molecules or materials absorbed from the cytosol without affecting other cellular operations.
- **Transport.** Materials can travel from place to place within the ER.
- **Detoxification.** The ER can absorb drugs or toxins and neutralize them with enzymes.

The ER forms hollow tubes, flattened sheets, and chambers called **cisternae** (sis-TUR-nē; a reservoir for water). Two types of ER exist: *smooth endoplasmic reticulum* (SER) and *rough endoplasmic reticulum* (RER) (**Figure 3-5**). The term *smooth* refers to the fact that no fixed ribosomes are associated with the smooth endoplasmic reticulum, while the fixed ribosomes on the outer surface of the rough endoplasmic reticulum give it a beaded, grainy, or rough appearance.

The amount of endoplasmic reticulum and the proportion of RER to SER vary with the type of cell and its ongoing activities. For example, pancreatic cells that manufacture digestive enzymes contain an extensive RER, but the SER is relatively small. The situation is just the reverse in the cells of reproductive organs that synthesize steroid hormones.

Smooth Endoplasmic Reticulum. The **smooth endoplasmic reticulum (SER)** is involved with the synthesis of lipids, fatty acids, and carbohydrates; the sequestering, or isolating, of

Figure 3-5 The Endoplasmic Reticulum.

calcium ions; and the detoxification of drugs. Important functions of the SER include the following:

- *synthesis of the phospholipids and cholesterol* needed for maintenance and growth of the plasma membrane, ER, nuclear membrane, and Golgi apparatus in all cells;
- *synthesis of steroid hormones*, such as androgens and *estrogens* (the dominant sex hormones) in reproductive organs;
- *synthesis and storage of glycerides, especially triglycerides*, in liver cells and fat cells; and
- *synthesis and storage of glycogen* in skeletal muscle and liver cells.

In muscle cells, neurons, and many other types of cells, the SER also adjusts the composition of the cytosol by absorbing and storing ions, such as Ca^{2+} , or large molecules. In addition, the SER in liver and kidney cells detoxifies or inactivates drugs.

Rough Endoplasmic Reticulum. The **rough endoplasmic reticulum (RER)** functions as a combination workshop and shipping warehouse, because the fixed ribosomes on the RER synthesize proteins. Many of these newly synthesized proteins are then chemically modified in the RER and packaged for export to their next destination, the Golgi apparatus.

The new polypeptide chains produced at fixed ribosomes are released into the cisternae of the RER. Inside the RER, each protein assumes its secondary and tertiary structures. Some of the proteins are enzymes that function inside the endoplasmic reticulum. Other proteins are chemically modified by the attachment of carbohydrates, creating glycoproteins.

Most proteins and glycoproteins produced by the RER are packaged into small membranous sacs that pinch off from the

tips of the cisternae. These **transport vesicles** then deliver their contents to the Golgi apparatus.

The Golgi Apparatus

When a transport vesicle carries a newly synthesized protein or glycoprotein that is destined for export from the cell, it travels from the ER to the **Golgi (GŌL-jē) apparatus**, or **Golgi complex**, an organelle that looks a bit like a stack of dinner plates (**Figure 3–6**). This organelle typically consists of five or six flattened membranous discs called *cisternae*. A single cell may contain several of these organelles, most often near the nucleus.

The Golgi apparatus has the following major functions (**Spotlight Figure 3–7**). It:

- *modifies and packages secretions*, such as hormones or enzymes, for release from the cell;
- *adds or removes carbohydrates to or from proteins* to change protein structure and thus function;
- *renews or modifies the plasma membrane*; and
- *packages special enzymes within vesicles (lysosomes)* for use in the cytoplasm.

Lysosomes

Cells often need to break down and recycle large organic molecules and even complex structures like organelles. The breakdown process requires powerful enzymes, and it often generates toxic chemicals that could damage or kill the cell. **Lysosomes** (LĪ-sō-sōmz; *lyso-*, a loosening + *soma*, body) are vesicles produced by the Golgi apparatus that provide an isolated environment for potentially dangerous chemical reactions.

Figure 3–6 The Golgi Apparatus.

SPOTLIGHT

Figure 3-7

Protein Synthesis, Processing, and Packaging

The Golgi apparatus plays a major role in modifying and packaging newly synthesized proteins. Some proteins and glycoproteins synthesized in the rough endoplasmic reticulum (RER) are delivered to the Golgi apparatus by transport vesicles. Here's an 8 step summary of the process, beginning with DNA.

1 Protein synthesis begins when a gene on DNA produces messenger RNA (mRNA), the template for protein synthesis.

2 The mRNA leaves the nucleus and attaches to a free ribosome in the cytoplasm, or a fixed ribosome on the RER.

3a Proteins constructed on free ribosomes are released into the cytosol for use within the cell.

3b Protein synthesis on fixed ribosomes occurs at the RER. The newly synthesized protein folds into its three-dimensional shape.

4 The proteins are then modified within the ER. Regions of the ER then bud off, forming transport vesicles containing modified proteins and glycoproteins.

5 The transport vesicles carry the proteins and glycoproteins generated in the ER toward the Golgi apparatus. The transport vesicles then fuse to create the forming *cis* face ("receiving side") of the Golgi apparatus.

6 Multiple transport vesicles combine to form cisternae on the *cis* face. Further protein and glycoprotein modification and packaging occur as the cisternae move toward the maturing (*trans*) face. Small transport vesicles return resident Golgi proteins to the forming *cis* face for reuse.

7 The maturing *trans* face ("shipping side") generates vesicles that carry modified proteins away from the Golgi apparatus. One type of vesicle becomes a lysosome, which contains digestive enzymes.

8 Two other types of vesicles proceed to the plasma membrane: secretory and membrane renewal. **Secretory vesicles** fuse with the plasma membrane and empty their products outside the cell by exocytosis. **Membrane renewal vesicles** add new lipids and proteins to the plasma membrane.

Figure 3-8 Lysosome Functions. Primary lysosomes, formed by the Golgi apparatus, contain inactive enzymes. They may be activated under any of the three basic conditions indicated here.

These vesicles contain digestive enzymes that break organic polymers into monomers. Lysosomes are small, often spherical bodies with contents that look dense and dark in electron micrographs.

Lysosomes have several functions (**Figure 3-8**). One is to remove damaged organelles. *Primary lysosomes* contain inactive enzymes. When these lysosomes fuse with the membranes of damaged organelles (such as mitochondria or fragments of the endoplasmic reticulum), the enzymes are activated and *secondary lysosomes* are formed. The enzymes then break down the contents. The cytosol reabsorbs released nutrients, and the remaining material is expelled from the cell.

Lysosomes also destroy bacteria (as well as liquids and organic debris) that enter the cell from the extracellular fluid. The cell encloses these substances in a small portion of the plasma membrane, which is then pinched off to form a transport vesicle, or *endosome*, in the cytoplasm. (We discuss this method of transporting substances into the cell, called *endocytosis*, in Section 3-6.) Then a primary lysosome fuses with the vesicle, forming a secondary lysosome. Activated

enzymes inside break down the contents and release usable substances, such as sugars or amino acids. In this way, the cell both protects itself against harmful substances and obtains valuable nutrients.

Lysosomes also do essential cleanup and recycling inside the cell. For example, when muscle cells are inactive, lysosomes gradually break down their contractile proteins. (This mechanism accounts for the reduction in muscle mass that accompanies aging.) The process is usually precisely controlled, but in a damaged or dead cell, the regulatory mechanism fails as lysosome membranes become increasingly permeable. Lysosomes then disintegrate, releasing enzymes that become activated within the cytosol. These enzymes rapidly destroy the cell's proteins and organelles in a process called **autolysis** (aw-TOL-i-sis; *auto-*, self). Although many factors seem to increase lysosome membrane permeability, we do not yet know how to control lysosomal activities.

Peroxisomes

Peroxisomes are smaller than lysosomes and carry a different group of enzymes. In contrast to lysosomes, which are produced at the Golgi apparatus, new peroxisomes are produced by the growth and subdivision of existing peroxisomes. Their enzymes are produced at free ribosomes and transported from the cytosol into the peroxisomes by carrier proteins.

Peroxisomes absorb and break down fatty acids and other organic compounds. As they do so, peroxisomes generate hydrogen peroxide (H_2O_2), a potentially dangerous free radical. Catalase, the most abundant enzyme within the peroxisome, then breaks down the hydrogen peroxide to oxygen and water. In this way, peroxisomes protect the cell from the potentially damaging effects of the free radicals produced during catabolism. Peroxisomes are present in all cells, but their numbers are highest in metabolically active cells, such as liver cells.

Clinical Note Lysosomal Storage Diseases

Problems in producing lysosomal enzymes cause more than 30 serious diseases affecting children. In these conditions, called *lysosomal storage diseases*, the lack of a specific lysosomal enzyme results in the buildup of wastes and debris that lysosomes normally remove and recycle. Affected individuals may die when vital cells, such as those of the heart, can no longer function.

Mitochondria

The cells of all living things require energy to carry out the functions of life. The organelles that produce energy in the form of ATP molecules are the **mitochondria** (mĭ-tō-KON-drē-uh; singular, *mitochondrion*; *mitos*, thread + *chondrion*, granule). The number of mitochondria in a particular cell varies with the cell's energy demands. These organelles may account for 30% of the volume of a heart muscle cell, yet they are absent in red blood cells.

Mitochondria have an unusual double membrane (Figure 3-9a). The outer membrane surrounds the organelle.

The inner membrane contains numerous folds called **cristae** (KRIS-tē), which surround the fluid contents, or **matrix**, of the mitochondrion. Cristae increase the membrane surface area in contact with the matrix. This allows for more attached protein complexes and enzymes involved in making ATP from ADP and P_i (inorganic phosphate). Metabolic enzymes in the matrix catalyze reactions that release carbon dioxide and provide some additional energy for cellular functions.

Mitochondria contain their own DNA (mtDNA) and ribosomes. The mtDNA codes for small amounts of RNA and

Figure 3-9 Mitochondria.

- b** This is an overview of the role of mitochondria in energy production. Mitochondria absorb oxygen and short carbon chains, such as pyruvate, and they generate carbon dioxide, ATP, and water.

What are the two reactants shown here that are necessary for energy production?
What are the three products shown here that result from this reaction?

polypeptide molecules. The polypeptides are used in enzymes required for energy production. Although mitochondria contain their own genetic system, their functions depend on imported proteins coded by nuclear DNA.

3

Most chemical reactions that release energy take place in the mitochondria, yet most cellular activities that require energy occur in the surrounding cytoplasm. For this reason, cells must store energy in a form that can be moved from place to place. Recall from Chapter 2 that cellular energy is stored and transferred in the form of *high-energy bonds*. The best example is the high-energy bond that attaches an inorganic phosphate ion (P_i) to adenosine diphosphate (ADP), forming the high-energy compound *adenosine triphosphate* (ATP). Cells can then break this high-energy bond under controlled conditions, reconvert ATP to ADP and phosphate and releasing energy for the cell's use when and where it is needed.

Many cells generate ATP and other high-energy compounds as they break down carbohydrates, especially glucose. We examine the entire process in Chapter 25, but a few basic concepts now will help you follow discussions of muscle contraction, neuron function, and endocrine function in Chapters 10–18.

Most ATP is produced inside mitochondria, but the first steps take place in the cytosol (**Figure 3–9b**). A reaction sequence called **glycolysis** (*glycos*, sugar + *-lysis*, a loosening) breaks down a glucose molecule into two molecules of *pyruvate*. Mitochondria then absorb the pyruvate molecules.

In the mitochondrial matrix, a carbon dioxide (CO_2) molecule is removed from each absorbed pyruvate molecule. The remainder then enters the **citric acid cycle** (also known as the *Krebs cycle* and the *tricarboxylic acid cycle* or *TCA cycle*). The citric acid cycle is an enzymatic pathway that breaks down the absorbed pyruvate.

The remnants of pyruvate molecules contain carbon, oxygen, and hydrogen atoms. The carbon and oxygen atoms are released as carbon dioxide, which diffuses out of the cell. The hydrogen atoms are delivered to carrier protein complexes in the cristae. There the electrons are removed from the hydrogen atoms and passed along a chain of coenzymes and ultimately transferred to oxygen atoms. The energy released during these steps indirectly supports the enzymatic conversion of ADP to ATP.

Because mitochondrial activity requires oxygen, this method of ATP production is known as **aerobic metabolism** (*aer*, air + *bios*, life), or *cellular respiration*. Aerobic metabolism in mitochondria produces about 95% of the ATP needed to keep a cell alive. (Enzymatic reactions, including glycolysis, in the cytosol produce the rest.)

Membrane Flow

When the temperature changes markedly, people change their clothes. Similarly, when a cell's environment changes, it changes the structure and properties of its plasma membrane. Except

Clinical Note Free Radicals

Throughout a typical day or after exposure to pollution, cells generate free radicals. *Free radicals* are highly reactive atoms or molecules that contain an unpaired electron “seeking” the electrochemical stability of another electron. Common free radicals containing oxygen are known as reactive oxygen species (ROS). Free radicals such as ROS can damage proteins, DNA, and lipids. They prevent proteins from assuming their functional quaternary structure, DNA becomes cross-linked and unable to replicate, and the phospholipid bilayer of membranous organelles and the plasma membrane itself is pierced. Oxidative damage by free radicals underlies aging and numerous disorders such as Alzheimer's disease.

for mitochondria, all membranous organelles in the cell are either interconnected or in communication through the movement of vesicles. The membranes of the rough endoplasmic reticulum and smooth endoplasmic reticulum are continuous and are connected to the nuclear envelope. Transport vesicles connect the endoplasmic reticulum with the Golgi apparatus, and secretory vesicles link the Golgi apparatus with the plasma membrane. Finally, vesicles forming at the exposed surface of the cell remove and recycle segments of the plasma membrane. This continuous movement and exchange of membrane segments is called **membrane flow**, or *membrane trafficking*. In an actively secreting cell, an area equal to the entire membrane surface may be replaced each hour. This process was shown in **Spotlight Figure 3–7**.

Membrane flow is an example of the dynamic nature of cells. It provides a way for cells to change the characteristics of their plasma membranes by altering their lipids and the proteins serving as receptors, channels, anchors, and enzymes—as they grow, mature, or respond to a specific environmental stimulus.

Checkpoint

5. Explain the difference between the cytoplasm and the cytosol.

3-3 The nucleus contains DNA and enzymes essential for controlling cellular activities

Learning Outcome Explain the functions of the cell nucleus and discuss the nature and importance of the genetic code.

The **nucleus** is usually the largest and most obvious structure in a cell. While looking under a light microscope, the nucleus may be the only visible organelle. The nucleus is the control center for cellular operations. A single nucleus stores all the information needed to direct the synthesis of more than 100,000 different proteins in the human body. The nucleus determines cell structure and functions by controlling which proteins are synthesized, under what circumstances, and in what amounts. A cell without a nucleus cannot repair itself, so it will disintegrate within 3 or 4 months.

Structure of the Nucleus

Most cells contain a single nucleus, but exceptions exist. For example, skeletal muscle cells have many nuclei, but mature red blood cells have none. **Figure 3-10** details the structure of a typical nucleus. The nucleus is surrounded by a membranous nuclear envelope, which encloses its contents, including DNA.

Nuclear Envelope

Surrounding the nucleus and separating it from the cytosol is a **nuclear envelope**, a double membrane with its two layers separated by a narrow *perinuclear space* (*peri-*, around). At several locations, the nuclear envelope is connected to the rough endoplasmic reticulum (**Spotlight Figure 3-1**).

To direct processes that take place in the cytoplasm, the nucleus must receive information about conditions and activities

Figure 3-10 The Nucleus.

in other parts of the cell. Chemical communication between the nucleus and the cytoplasm takes place through openings in the nuclear envelope called **nuclear pores**. Each pore has about 50 associated proteins, forming a *nuclear pore complex*. Each nuclear pore complex regulates the transport of materials, such as RNA and other proteins, between the nucleus and the cytoplasm. They are large enough to allow ions and small molecules to enter or leave but are too small for DNA to pass freely.

Contents of the Nucleus

The fluid portion of the nucleus is called the *nucleoplasm*. The nucleoplasm contains the **nuclear matrix**, a network of fine filaments that provides structural support and may be involved in the regulation of genetic activity. The nucleoplasm also contains ions, enzymes, RNA and DNA nucleotides, small amounts of RNA, and DNA.

In addition, most nuclei contain several dark-staining areas called **nucleoli** (nū-KLĒ-ō-lī; singular, *nucleolus*). Nucleoli are transient nuclear organelles that synthesize ribosomal RNA. They also assemble the ribosomal subunits, which then enter the cytoplasm through nuclear pores. Nucleoli are composed of RNA, enzymes, and proteins called **histones**. The nucleoli form around portions of DNA that contain the instructions for producing ribosomal proteins and RNA. Nucleoli are most prominent in cells that manufacture large amounts of proteins, such as liver, nerve, and muscle cells, because those cells need large numbers of ribosomes.

The DNA in the nucleus stores the instructions for protein synthesis. Interactions between the DNA and the histones help determine which information is available to the cell at any moment. The organization of DNA within the nucleus of a nondividing cell and one preparing for cell division is shown in **Figure 3–11**. At intervals, the DNA strands wind around the histones, forming a complex known as a **nucleosome**. Such winding allows a great deal of DNA to be packaged in a small space.

The entire chain of nucleosomes may coil around other proteins. The degree of coiling varies, depending on whether cell division is under way. In cells that are not dividing, the nucleosomes are loosely coiled within the nucleus, forming a tangle of fine filaments known as **chromatin**. Chromatin gives the nucleus a clumped, grainy appearance. Just before cell division begins, the coiling becomes tighter, forming distinct structures called **chromosomes** (*chroma*, color). In humans, the nuclei of somatic cells contain 23 pairs of chromosomes. One member of each pair is derived from the biological mother and one from the biological father.

Information Storage in the Nucleus

As we saw in Chapter 2, each protein molecule consists of a unique sequence of amino acids. Any “recipe” for a protein must specify the order of amino acids in the polypeptide chain.

Figure 3–11 The Organization of DNA within the Nucleus. DNA strands are coiled around histones to form nucleosomes. Nucleosomes form coils that may be very tight or rather loose. In cells that are not dividing, the DNA is loosely coiled, forming a tangled network known as chromatin. When the coiling becomes tighter, as it does in preparation for cell division, the DNA becomes visible as distinct structures called chromosomes. (Terms associated with cell division are highlighted with an asterisk [*] and discussed in **Spotlight Figure 3–23**.)

How is DNA organized in the nucleus when the cell is prepared for division? How is DNA organized in the nucleus when the cell is not dividing?

This information is stored in the chemical structure of the DNA strands in the nucleus. The chemical “language” the cell uses is known as the **genetic code**. An understanding of the genetic code enables us to learn how cells build proteins and how various structural and functional characteristics are inherited from generation to generation.

How does the genetic code work? Recall the basic structure of nucleic acids described in Chapter 2. A single DNA molecule consists of a pair of DNA strands held together by hydrogen bonding between complementary nitrogenous bases. Information is stored in the sequence of nitrogenous bases along the length of the DNA strands. Those nitrogenous bases are adenine (A), thymine (T), cytosine (C), and guanine (G).

The genetic code is called a *triplet code* because a sequence of three nitrogenous bases represents a single amino acid. Thus, the information encoded in the sequence of nitrogenous bases must be read in groups of three. For example, the triplet thymine–guanine–thymine (TGT) on one DNA strand, called the *coding strand*, is the code for the amino acid cysteine. More than one triplet may represent the same amino acid, however. For example, the DNA triplet thymine–guanine–cytosine (TGC) also codes for cysteine.

A **gene** is the functional unit of heredity. It is the sequence of nucleotides of a DNA strand that specifies the amino acids needed to produce a specific protein. The needed number of triplet nucleotides, each coding for an amino acid, depends on the size of the polypeptide represented. A relatively short polypeptide chain might need fewer than 100 triplets, but the instructions for building a large protein might involve 1000 or more triplets.

Not all nucleotide sequences of a DNA strand carry instructions for assembling proteins. Some sequences contain instructions for synthesizing ribosomal RNA or another type that we discuss shortly, called *transfer RNA*. Others have a regulatory function, and still others have as yet no known function.

3-4 DNA controls protein synthesis, cell structure, and cell function

Learning Outcome Summarize the role of DNA in protein synthesis, cell structure, and cell function.

The DNA of the nucleus controls cell structure and function through the synthesis of specific proteins. **Protein synthesis** is the assembling of functional polypeptides in the cytoplasm. The major events of protein synthesis are transcription and translation.

Regulation of Transcription by Gene Activation

Each DNA molecule contains thousands of genes—the information needed to synthesize thousands of proteins. Normally, the genes are tightly coiled, and histones bound to the DNA keep the genes inactive. Before a gene can affect a cell, the portion of the DNA molecule containing that gene must be uncoiled and the histones temporarily removed in a process called **gene activation**.

The factors controlling this process are only partially understood. We know, however, that every gene contains segments

responsible for regulating its own activity. In effect, these are triplets of nucleotides that say “read this message” or “do not read this message,” “message starts here,” or “message ends here.” These “read me,” “don’t read me,” and “start” signals form a special region of DNA called the *promoter* at the start of each gene. Each gene ends with a “stop” signal. Gene activation begins with the temporary disruption of the weak hydrogen bonds between the nitrogenous bases of the two DNA strands and the removal of the histone that guards the promoter.

Transcription of DNA into mRNA

Transcription is the synthesis of RNA from a DNA template. The use of the term *transcription* makes sense, as it means “to copy” or “rewrite.”

All three types of RNA are formed through the transcription of DNA, but we focus here on the transcription of **messenger RNA (mRNA)**, which carries the information needed to synthesize proteins. The synthesis of mRNA is essential because DNA is too large to leave the nucleus. Instead, its information is copied to messenger RNA, which is smaller and *can* leave the nucleus and carry the information to the cytoplasm, where protein synthesis takes place.

Recall that the two DNA strands in a gene are complementary. The strand containing the triplets that specify the sequence of amino acids in the polypeptide is the **coding strand**. The other strand, called the **template strand**, contains

Clinical Note DNA Fingerprinting

Every nucleated somatic cell in the body carries a set of 46 chromosomes (23 pairs) that are copies of the set formed at fertilization. Not all the DNA of these chromosomes codes for proteins. Within the non-protein-coding DNA are regions called short tandem repeats (STRs), which contain the same nucleotide sequence repeated over and over. The number of STRs and the number of repetitions vary among individuals.

In the United States, 13 core STRs are used for identifying individuals by *DNA fingerprinting*. The individual differences are reflected in the different lengths of these STRs. The chance that any two individuals, other than identical twins, will have the same length and pattern of repeating DNA segments in 13 STRs is approximately one in 575 trillion. For this reason, individuals can be identified based on their DNA pattern, just as they can on the basis of a fingerprint. Skin cells, semen, hair root cells, or cheek cells can serve as the DNA source. Information from DNA fingerprinting has been used to convict or acquit people accused of violent crimes, such as rape or murder. The U.S. Crime Act of 1994 allowed the FBI to establish and maintain the National DNA Index System.

complementary triplets that will be used as a template for mRNA production. The resulting mRNA will have a nucleotide sequence identical to that of the coding strand, but with uracil substituted for thymine.

The Process of Transcription

The steps in transcription are illustrated in **Figure 3-12**:

1 RNA Polymerase Binding. Once the DNA strands have separated and the histones have been removed to expose the promoter, transcription can begin. The key event is the binding of the enzyme **RNA polymerase** to the promoter of a gene on the template strand.

2 RNA Polymerase Nucleotide Linking. RNA polymerase promotes hydrogen bonding between the nitrogenous bases of the template strand nucleotides and complementary

nucleotides in the nucleoplasm. This enzyme begins at a “start” signal in the promoter region. It then strings nucleotides together by covalent bonding. The RNA polymerase travels along the DNA strand, interacting with only a small portion of the template strand at any one time. The complementary DNA strands separate in front of the enzyme as it moves one nucleotide at a time, and the strands then reassociate behind it.

The enzyme collects additional nucleotides and attaches them one by one to the growing chain. The nucleotides involved are characteristic of RNA, not of DNA. In other words, RNA polymerase can attach adenine, guanine, cytosine, or uracil, but never thymine. For this reason, wherever an A occurs in the DNA strand, the enzyme attaches a U rather than a T to the growing mRNA strand. In this way, RNA polymerase assembles a complete strand of mRNA.

Figure 3-12 mRNA Transcription. In this figure, a small portion of a single DNA molecule, containing a single gene, is undergoing transcription. **1** The two DNA strands separate, and RNA polymerase binds to the promoter of the gene. **2** The RNA polymerase moves from one nucleotide to another along the length of the template strand. At each site, complementary RNA nucleotides form hydrogen bonds with the DNA nucleotides of the template strand. The RNA polymerase then strings the arriving nucleotides together into a strand of mRNA. **3** On reaching the stop signal at the end of the gene, the RNA polymerase and the mRNA strand detach, and the two DNA strands reassociate.

Be sure to view the
SmartArt
video for this figure.

Notice that the nucleotide sequence of the DNA template strand determines the nucleotide sequence of the mRNA strand. Each DNA triplet corresponds to a sequence of three nucleotides in the mRNA strand. Such a three-base mRNA sequence is called a **codon** (KŌ-don). Codons contain nitrogenous bases that are complementary to those of the triplets in the DNA template strand. For example, if the DNA triplet is TCG, the corresponding mRNA codon will be AGC. This method of copying ensures that the mRNA exactly matches the coding strand of the gene (except for the substitution of uracil for thymine).

3 Detachment of mRNA. At the “stop” signal, the enzyme and the mRNA strand detach from the DNA strand, and transcription ends. The complementary DNA strands now complete their reassociation as hydrogen bonding takes place again between complementary base pairs.

RNA Processing

The nucleotide sequence of each gene includes several triplets that are not needed to build a functional protein. As a result, the mRNA strand assembled during transcription, sometimes called immature mRNA or *pre-mRNA*, must be “edited” before it leaves the nucleus to direct protein synthesis. In this **RNA processing**, noncoding intervening sequences, called **introns**, are snipped out, and the remaining coding segments, or **exons**, are spliced together. The process creates a much shorter, functional strand of mRNA that then enters the cytoplasm through a nuclear pore.

Intron removal is extremely important and tightly regulated. An error in the editing will produce an abnormal protein with potentially disastrous results. Moreover, we now know that by changing the editing instructions and removing different introns, a single gene can produce mRNAs that code for several different proteins. Some introns, however, act as enzymes to catalyze their own removal. How this variable editing is regulated is unknown.

Translation from mRNA into a Polypeptide

Translation is the formation of a linear chain of amino acids, a polypeptide, using the information from an mRNA strand. Again, the name makes sense: To *translate* is to present the same information in a different language. In this case, a message written in the “language” of nucleic acids (the sequence of nitrogenous bases) is translated into the “language” of proteins (the sequence of amino acids in a polypeptide chain). Each mRNA codon designates a particular amino acid to be inserted into the polypeptide chain.

The amino acids are provided by **transfer RNA (tRNA)**, a relatively small and mobile type of RNA. Each tRNA molecule binds and delivers a specific type of amino acid. More than 20 kinds of transfer RNA exist—at least one for each of the 20 amino acids used in protein synthesis.

A tRNA molecule has a “tail” that binds an amino acid. About midway along its length, the nucleotide chain of the

Table 3–1 Examples of the Genetic Code

DNA Triplet				
Template Strand	Coding Strand	mRNA Codon	tRNA Anticodon	Amino Acid
AAA	TTT	UUU	AAA	Phenylalanine
AAT	TTA	UUA	AAU	Leucine
ACA	TGT	UGU	ACA	Cysteine
CAA	GTT	GUU	CAA	Valine
TAC	ATG	AUG	UAC	Methionine
TCG	AGC	AGC	UCG	Serine
GGC	CCG	CCG	GGC	Proline
CGG	GCC	GCC	CGG	Alanine

tRNA forms a tight loop that can interact with an mRNA strand. The loop contains three nitrogenous bases that form an **anticodon**. During translation, the anticodon bonds with a complementary mRNA codon. The anticodon base sequence indicates the type of amino acid carried by the tRNA. For example, a tRNA with the anticodon GGC always carries the amino acid *proline*, whereas a tRNA with the anticodon CGG carries *alanine*. **Table 3–1** lists examples of several codons and anticodons that specify individual amino acids and summarizes the relationships among DNA template and coding strand triplets, codons, anticodons, and amino acids.

Clinical Note Mutations

Mutations are permanent changes in a cell’s DNA that affect the nucleotide sequence of one or more genes. The simplest is a *point mutation*, a change in a single nucleotide that affects one codon. The triplet code has some flexibility because several different codons can specify the same amino acid. But a point mutation that produces a codon that specifies a different amino acid will usually change the structure of the completed protein. A single change in the amino acid sequence of a structural protein can prove fatal. Certain cancers and two potentially lethal blood disorders, *thalassemia* and *sickle cell anemia*, result from changes in a single nucleotide.

Several hundred inherited disorders have been traced to abnormalities in enzyme or protein structure that reflect single changes in the nucleotide sequence. More extensive mutations, such as additions or deletions of nucleotides, can affect multiple codons in one gene or in several adjacent genes. They can also affect the structure of one or more chromosomes.

Most mutations occur during DNA replication, when cells are duplicating their DNA in preparation for cell division. A single cell, a group of cells, or an entire individual may be affected. Entire organisms are affected when the changes are made early in development.

Figure 3–13 The Process of Translation.

Be sure to view the
SmartArt
video for this figure.

Initiation

Translation begins as the mRNA strand binds to a small ribosomal subunit at the start codon. The attachment of tRNA and the subsequent binding of the large ribosomal subunit creates a functional ribosome, with the mRNA nestled in the gap between the small and the large ribosomal subunits.

1 Binding of Small Ribosomal Subunit to mRNA

Translation begins with the small ribosomal unit binding to an mRNA strand. An initiator tRNA carrying a specific amino acid, methionine, binds to the mRNA “start” codon AUG.

2 Formation of Functional Ribosome

The small and large ribosomal units join together and enclose the mRNA and tRNA. The large ribosomal subunit has three sites for tRNA binding, called the **E** site (Exit), **P** site (Polypeptide building), and **A** site (Arrival).

During translation, each codon along the mRNA strand binds a complementary anticodon on a tRNA molecule. For example, if the mRNA has the three-codon sequence AUG–CCG–AGC, it will bind to three tRNAs with anticodons UAC, GGC, and UCG, respectively. The amino acid sequence of the polypeptide chain depends on the resulting sequence of codons along the mRNA strand. In this case, the amino acid sequence in the resulting polypeptide would be methionine–proline–serine. (You can follow the correspondence among codons, anticodons, and amino acids in [Table 3–1](#). For a complete table of

the mRNA codons and which amino acids and start or stop signals they represent, see Appendix D at the back of the book.)

Recall that ribosomes are organelles that play a key role in protein synthesis. Recall that a functional ribosome consists of two subunits, a small ribosomal subunit and a large ribosomal subunit. At the beginning of the translation process, a small and a large ribosomal subunit must join with an mRNA strand. **Figure 3–13** illustrates the three phases of the translation process: *initiation*, *elongation*, and *termination*. Please study this figure carefully before going on.

Elongation

In elongation, amino acids are added one by one to the growing polypeptide chain, as the ribosome moves along the mRNA strand. Translation proceeds swiftly, producing a typical protein in about 20 seconds. Although only two mRNA codons are “read” by a ribosome at any one time, many ribosomes can bind to a single mRNA strand, and a multitude of identical polypeptides may be quickly and efficiently produced.

3 Formation of Peptide Bond

A second tRNA then arrives at the A site of the ribosome, carrying amino acid 2. Its anticodon binds to the second codon of the mRNA strand. Ribosomal enzymes now remove amino acid 1 from the first tRNA in the P site and attach it to amino acid 2 with a peptide bond.

4 Extension of Polypeptide

The ribosome now moves one codon farther along the length of the mRNA strand. A third tRNA arrives at the A site, bearing amino acid 3. The first tRNA then detaches from the E site of the ribosome and reenters the cytosol. It can pick up another amino acid molecule in the cytosol and repeat the process.

Termination

Elongation ends when the ribosome reaches the stop codon at the end of the mRNA strand. The mRNA strand remains intact, and it can interact with other ribosomes to create additional copies of the same polypeptide chain.

5 Completion and Release of Polypeptide

Elongation continues until the ribosome reaches a stop codon. Termination occurs as a protein-release factor bonds with the stop codon and the completed polypeptide is released. The ribosomal subunits then separate, freeing the mRNA strand.

How DNA Controls Cell Structure and Function

As we noted previously, the DNA of the nucleus controls the cell by directing the synthesis of specific proteins. By controlling protein synthesis, virtually every aspect of cell structure and function can be regulated.

How is cell structure and function regulated at the DNA level? How does the nucleus “know” which genes to activate or deactivate (silence) to maintain cellular homeostasis? Changes in the extracellular environment may result in ions or molecules

entering the cell directly through membrane channels or by binding to membrane receptors that then alter the intracellular (cytoplasmic) environment. Such direct entry into the cell or binding of ligands can initiate chemical *signaling pathways* that form intracellular signaling molecules. Either situation may trigger the activation or inactivation of cytoplasmic enzymes and provide short-term adjustments that maintain homeostasis.

Alternatively, substances that cross the plasma membrane, such as chemical messengers, hormones, or products that form from a signaling pathway, may enter the nucleus through

nuclear pores and bind to specific receptors or promoters along the DNA strands. The result is a change in genetic activity that provides long-term homeostatic adjustments affecting the cell's biochemical and physical characteristics. For example, synthesizing additional enzymes, fewer enzymes, or different enzymes can change the biochemical processes under way in the cell. Changes in the physical structure of the cell result from alterations in the rates or types of structural proteins that are synthesized. Long-term changes in cell structure and function also occur as part of growth, development, and aging. (We discuss signaling pathways within cells in Chapter 18.)

Continual communication takes place between the cytoplasm and the extracellular fluid across the plasma membrane, and what crosses the plasma membrane today may alter gene activity tomorrow. In the next two sections, we examine how the plasma membrane selectively regulates the passage of materials into and out of the cell.

See the blue Answers tab at the back of the book.

3-5 Diffusion is a passive transport mechanism that assists membrane passage of solutes and water

Learning Outcome Describe the processes of cellular diffusion and osmosis and explain their role in physiological systems.

The plasma membrane is an effective barrier between the cytoplasm and the extracellular fluid. A consequence is that conditions inside the cell can be much different from conditions outside the cell. However, the barrier cannot be perfect because cells are not self-sufficient. Each day cells require nutrients for energy to stay alive and function normally. They also generate wastes that must be removed. The body has passageways and openings for nutrients, gases, and wastes, but a continuous, relatively uniform membrane surrounds the cell. So how do materials—whether nutrients or wastes—get across the plasma membrane without damaging it or reducing its effectiveness as a barrier?

The key to answering this question is **permeability**, the property of the plasma membrane that determines precisely which substances can enter or leave the cytoplasm. A membrane through which nothing can pass is **impermeable**. A membrane through which any substance can pass without difficulty is **freely permeable**. Plasma membranes are called **selectively permeable**, however, because their permeability lies somewhere between those extremes.

A selectively permeable membrane permits the free passage of some materials and restricts the passage of others. The distinction may be based on size, electrical charge, molecular shape, lipid solubility, or other factors. Cells differ in their permeabilities, depending on the lipids and proteins in the plasma membrane and how these components are arranged.

Passage across the membrane is either passive or active. *Passive processes* move ions or molecules across the plasma membrane with no expenditure of energy by the cell. *Active processes* require that the cell expend energy, generally in the form of ATP.

We cover the main passive process, *diffusion*, and a special case of diffusion called *osmosis*, in this section. In the next section, we cover carrier-mediated transport, which can be passive or active, and vesicular transport, which is always an active process.

Diffusion

Driven by thermal energy, ions and molecules are constantly in motion, colliding and bouncing off one another and off obstacles in their paths. The movement is both passive and random: A molecule can bounce in any direction. One result of this continuous random motion is that, over time, the molecules in any given space will tend to become evenly distributed. This distribution process, the net movement of a substance from an area of higher concentration to an area of lower concentration, is called **diffusion**. The difference between the high and low concentrations of a substance is a **concentration gradient** (and thus a potential energy gradient). Because of its net movement, diffusion is often described as proceeding “down a concentration gradient” or “downhill.”

Diffusion tends to eliminate concentration gradients. After a gradient has been eliminated, the molecular motion continues, but net movement no longer occurs in any particular direction. (For simplicity, we restrict use of the term *diffusion* to the directional movement that eliminates concentration gradients—a process sometimes called *net diffusion*.)

Diffusion in air and water is a slow process, and it is most important over very short distances. A simple, everyday example gives a mental image of how diffusion works. Consider what happens when a colored sugar cube is dropped into water (**Figure 3-14**). Placing the cube in a large volume of clear water sets up a steep concentration gradient for both ingredients as they dissolve: The sugar and dye concentrations are higher near the cube and negligible elsewhere. As time passes, the dye and sugar molecules spread through the solution until they are distributed evenly. However, compared to a cell, a beaker of water is enormous, and additional factors (which we will ignore) account for dye and sugar distribution over distances of centimeters as opposed to micrometers.

Figure 3–14 Diffusion.

Diffusion is important in body fluids because it tends to eliminate local concentration gradients. For example, every cell in the body generates carbon dioxide (CO_2), so the intracellular CO_2 concentration is fairly high. The CO_2 concentration is lower in the surrounding interstitial fluid, and lower still in the circulating blood. Plasma membranes are freely permeable to CO_2 , so it can diffuse down its concentration gradient. The CO_2 travels from the cell's interior into the interstitial fluid and then into the bloodstream, for eventual delivery to the lungs.

To be effective, the diffusion of nutrients, wastes, and dissolved gases must keep pace with the demands of active cells. Several important factors influence diffusion rates:

- **Distance.** The shorter the distance, the more quickly concentration gradients are eliminated. In the human body, most cells are within $25\ \mu\text{m}$ of a blood vessel.
- **Ion and Molecule Size.** The smaller the ion and molecule size, the faster its rate of diffusion. Ions and small organic molecules, such as glucose, diffuse more rapidly than do large proteins.
- **Temperature.** The higher the temperature, the faster the diffusion rate. Diffusion proceeds somewhat quicker at human body temperature (about 37°C , or 98.6°F) than at cooler environmental temperatures.
- **Concentration Gradient.** The steeper the concentration gradient, the faster diffusion proceeds. For example, when cells become more active, they use more oxygen, so the intracellular concentration of oxygen decreases. This change increases the concentration gradient of oxygen between the inside of the cell (somewhat low) and the interstitial fluid outside (somewhat high). The rate of oxygen diffusion into the cell then increases.
- **Electrical Forces.** Opposite electrical charges (+ and –) attract each other, and like charges (+ and + or – and –) repel each other. The cytoplasmic (inner) surface of the plasma membrane has a net negative charge relative to the extracellular (outer) surface. This negative charge tends to attract positive ions from the extracellular fluid into the cell, while repelling the entry of negative ions.

Clinical Note Drugs and the Plasma Membrane

Many clinically important drugs affect the plasma membrane. For some anesthetics, such as chloroform, ether, halothane, and nitrous oxide, potency is directly correlated with their lipid solubility. High lipid solubility speeds the drug's entry into cells and enhances its ability to block ion channels or change other properties of plasma membranes. These changes reduce the sensitivity of neurons and muscle cells. However, some common anesthetics have relatively low lipid solubility. For example, the local anesthetics *procaine* and *lidocaine* affect nerve cells by blocking sodium ion channels in their plasma membranes. This blockage reduces or eliminates the responsiveness of these cells to painful (or any other) stimuli.

An ion's or a molecule's concentration gradient, or *chemical gradient*, can work to enhance or detract from the electrical gradient. For example, interstitial fluid contains higher concentrations of sodium ions (Na^+) and chloride ions (Cl^-) than does cytosol. Both the concentration gradient and the electrical gradient favor diffusion of the positively charged sodium ions into the cell. In contrast, diffusion of the negatively charged chloride ions into the cell is favored by the chemical gradient but opposed by the electrical gradient. For any ion, the net result of the chemical and electrical forces acting on it is called the *electrochemical gradient*.

Diffusion across Plasma Membranes

In extracellular fluids, water and dissolved solutes diffuse freely. A plasma membrane, however, acts as a barrier that selectively restricts diffusion: Some substances pass through easily, but others cannot penetrate the membrane. An ion or a molecule can diffuse across a plasma membrane only by (1) crossing the lipid portion of the membrane by simple diffusion or (2) passing through a membrane channel (**Figure 3–15**).

Simple Diffusion. Alcohol, fatty acids, and steroids can enter cells easily, because they can diffuse through the lipid portions of the membrane. Lipid-soluble drugs, dissolved gases such as

oxygen and carbon dioxide, and water molecules also enter and leave our cells by diffusing through the phospholipid bilayer.

Channel-Mediated Diffusion. The situation is more complicated for ions and water-soluble compounds, which are not lipid-soluble. To enter or leave the cytoplasm, these substances must pass through a membrane channel.

Membrane channels are very small passageways created by transmembrane proteins. An average channel is about 0.8 nm in diameter. Water molecules can enter or exit freely, but even a small organic molecule, such as glucose, is too big to fit through the channels. Whether an ion can cross a particular membrane channel depends on many factors, including the size and charge of the ion, the size of the hydration sphere, and interactions between the ion and the channel walls. Membrane channels that are always open and allow ions to pass across the plasma membrane are called *leak channels*, or passive channels.

The mechanics of diffusion through membrane channels is more complex than simple diffusion. For example, the rate at which a particular ion diffuses across the membrane can be limited by the availability of suitable channels. However, many ions, including sodium, potassium, and chloride, move across the plasma membrane at rates comparable to those for simple diffusion.

Figure 3–15 Diffusion across the Plasma Membrane. The path a substance takes in crossing a plasma membrane depends on the substance's size and lipid solubility.

How do small water-soluble molecules and ions diffuse across the plasma membrane? How do lipid-soluble molecules diffuse across the plasma membrane?

Media resource available for this topic: A&P Flix: Membrane Transport

Osmosis: Diffusion of Water across Selectively Permeable Membranes

The net diffusion of water across a membrane is so important that it has a special name: **osmosis** (oz-MŌ-sis; *osmos*, a push). We use the term *osmosis* for the movement of water and the term *diffusion* for the movement of solutes.

Intracellular and extracellular fluids are solutions with a variety of dissolved materials. Each solute diffuses as though it were the only material in solution. The diffusion of sodium ions, for example, takes place only in response to a concentration gradient for sodium. A concentration gradient for another ion has no effect on the rate or direction of sodium ion diffusion.

Some solutes diffuse into the cytoplasm, others diffuse out, and a few (such as proteins) are unable to diffuse across the plasma membrane at all. Yet if we ignore the individual identities and simply count ions and molecules, we find that the *total* concentration of dissolved ions and molecules on each side of the plasma membrane stays the same. This state of equilibrium persists because a typical plasma membrane is freely permeable to water.

To understand the basis for such equilibrium, consider that whenever a solute concentration gradient exists, a concentration gradient for *water* also exists. Dissolved solute molecules occupy space that would otherwise be taken up by water molecules, so the higher the solute concentration, the lower the water concentration. As a result, *water molecules tend to flow*

across a selectively permeable membrane toward the solution with the higher solute concentration, because this movement is *down* the concentration gradient for water. Water moves until the water concentrations—and thus solute concentrations—are the same on each side of the membrane; in other words, water moves until a state of equilibrium is reached. Remember these basic characteristics of osmosis:

- Osmosis is the diffusion of water molecules across a selectively permeable membrane.
- Osmosis takes place across a selectively permeable membrane that is freely permeable to water, but not freely permeable to all solutes.
- In osmosis, water flows across a selectively permeable membrane toward the solution that has the higher concentration of solutes, because that is where the concentration of water is lower.

Osmosis and Osmotic Pressure

The process of osmosis and its pressure effect are diagrammed in **Figure 3-16**. **1** shows two solutions (A and B), with different solute concentrations, separated by a selectively permeable membrane. As osmosis takes place, water molecules cross the membrane until the solute concentrations in the two solutions are identical (**2**). For this reason, the volume of solution B increases

Figure 3-16 Osmosis. The osmotic pressure of solution B is equal to the amount of hydrostatic pressure required to stop the osmotic flow from solution A to solution B.

while that of solution A decreases. The greater the initial difference in solute concentrations, the stronger is the osmotic flow.

The **osmotic pressure** of a solution is an indication of the force with which pure water moves into that solution as a result of its solute concentration. We can measure a solution's osmotic pressure in several ways. For example, an opposing pressure can prevent the osmotic flow of water into the solution. Pushing against a fluid generates **hydrostatic pressure**. In **3** hydrostatic pressure opposes the osmotic pressure of solution B, so no net osmotic flow occurs.

Osmosis eliminates solute concentration differences more rapidly than solute diffusion. Why? In large part this happens because water molecules can also cross a membrane through abundant water channels called **aquaporins**, which exceed the number of solute channels, through which water can also pass. This difference results in a higher membrane permeability for water than for solutes.

Osmolarity and Tonicity

The total solute concentration in an aqueous solution is the solution's **osmolarity**, or **osmotic concentration**. The nature of the solutes, however, is often as important as the total osmolarity. Therefore, when we describe the effects of various osmotic solutions on cells, we usually use the term **tonicity** instead of osmolarity. A solution that does not cause an osmotic flow of water into or out of a cell is called isotonic (*iso-*, same + *tonos*, tension).

The terms *osmolarity* and *tonicity* do not always mean the same thing, although they are often used interchangeably. Osmolarity refers to the solute concentration of the solution, but tonicity is a description of how the solution affects the shape of a cell. For example, consider a solution with the same osmolarity as the intracellular fluid, but a higher concentration of one or more individual ions. What happens if a cell is put into this solution? If any of those ions can cross the plasma membrane and diffuse into the cell, the osmolarity of the intracellular fluid increases, and that of the extracellular solution decreases. Osmosis will then also occur, moving water into the cell. If the process continues, the cell will gradually inflate like a water balloon. In this example, the extracellular solution and the intracellular fluid were initially equal in osmolarity, but they were not isotonic.

However, when discussing osmosis we commonly compare the solute, or osmotic, concentrations between two solutions, such as intracellular and extracellular fluids. Three terms are used to describe the possible situations: (1) *isotonic* (the two solutions being compared have equal solute, or osmotic, concentrations), (2) *hypotonic* (the solution with the lower solute, or osmotic, concentration), and (3) *hypertonic* (the solution with the higher solute, or osmotic, concentration).

What visible effects do various osmotic solutions have on cells? **Figure 3-17a** shows a red blood cell (RBC) in an **isotonic** solution, where no osmotic flow takes place and the size and

shape of the cell look normal. But if a red blood cell is put into a **hypotonic** (*hypo-*, lower) solution, water will flow into the cell, causing it to swell up like a balloon (**Figure 3-17b**). The cell may eventually burst, releasing its contents. This event is **hemolysis** (*hemo-*, blood + *lysis*, a loosening). In contrast, a cell in a **hypertonic** (*hyper-*, higher) solution will lose water by osmosis. As it does, the cell shrivels and dehydrates. The shrinking of red blood cells is called **crenation** (**Figure 3-17c**).

In the emergency department, it is often necessary to give patients large volumes of fluid to combat severe blood loss or dehydration. The procedure used in many cases is called an intravenous, or IV, drip and the fluids enter a patient's vein. One fluid frequently administered is a 0.9% (0.9 g/dL) solution of sodium chloride (NaCl). This solution, called *normal saline*, approximates the normal osmotic concentration of extracellular fluids. It is used because sodium and chloride are the most abundant ions in the extracellular fluid. Little net movement of either ion across plasma membranes takes place, so normal saline is essentially isotonic to body cells. An alternative IV treatment uses an isotonic saline solution containing *dextran*, a carbohydrate that cannot cross plasma membranes. The dextran molecules elevate the osmolarity and osmotic pressure of the blood, and as water enters the blood vessels from the surrounding tissue fluid by osmosis, blood volume increases.

3-6 Carrier-mediated and vesicular transport assist membrane passage of specific substances

Learning Outcome Describe carrier-mediated transport and vesicular transport mechanisms used by cells to facilitate the absorption or removal of specific substances.

Besides diffusion, substances are taken into or removed from cells in two additional ways: carrier-mediated transport and vesicular transport. *Carrier-mediated transport* requires specialized integral membrane proteins. This type of transport can

Figure 3–17 Osmotic Flow across a Plasma Membrane. The smaller paired arrows in part **a** indicate an equilibrium with no net water movement. The larger arrows indicate the direction of osmotic water movement.

Describe the concentration of the intracellular fluid relative to the extracellular fluid in parts b and c.

be passive or active, depending on the substance transported and the nature of the transport mechanism. *Vesicular transport* involves moving materials within small membranous sacs, or *vesicles*. Vesicular transport is always an active process.

Carrier-Mediated Transport

In **carrier-mediated transport**, integral proteins bind specific ions or organic substrates and carry them across the plasma membrane. All forms of carrier-mediated transport have the following characteristics, which they share with enzymes:

- **Specificity.** Each carrier protein in the plasma membrane binds and transports only certain substances. For example, the carrier protein that transports glucose will not transport other simple sugars.
- **Saturation Limits.** The availability of substrate molecules and carrier proteins limits the rate of transport into or out of the cell, just as the availability of substrates and enzymes limits enzymatic reaction rates. When all the available carrier proteins are operating at maximum speed, the

carriers are said to be *saturated*. The rate of transport cannot increase further, regardless of the size of the concentration gradient.

- **Regulation.** Just as enzyme activity often depends on cofactors, the binding of other molecules, such as hormones, can affect the activity of carrier proteins. For this reason, hormones provide an important means of coordinating carrier protein activity throughout the body. We examine the interplay between hormones and plasma membranes when we study the endocrine system (Chapter 18) and metabolism (Chapter 25).

Many examples of carrier-mediated transport involve the movement of a single substrate molecule across the plasma membrane. However, a few carrier proteins may move more than one substrate at a time. We discuss two mechanisms, **symport** (cotransport) and **antiport** (countertransport). In **symport** the common carrier protein, known as a symporter, transports two different molecules or ions through a membrane in the same direction, either into or out of the cell.

Figure 3–18 Facilitated Diffusion. In facilitated diffusion, a molecule, such as glucose, binds to a specific receptor site on a carrier protein. This binding permits the molecule to diffuse across the plasma membrane. If the direction of the glucose concentration gradient is reversed, then facilitated diffusion would occur in the opposite direction.

In the facilitated diffusion of glucose, what determines the direction in which glucose molecules will be transported?

In **antiport** the carrier protein, known as an antiporter, transports two different molecules or ions through the membrane in opposite directions.

Let's look at two examples of carrier-mediated transport: *facilitated diffusion* and *active transport*.

Facilitated Diffusion

Many essential nutrients, such as glucose and amino acids, are insoluble in lipids and too large to fit through membrane channels. These substances can be passively transported across the membrane by carrier proteins in a process called **facilitated diffusion** (Figure 3–18). The molecule to be transported must first bind to a **receptor site** on the carrier protein. The shape of the protein then changes, moving the molecule across the plasma membrane and releasing it into the cytoplasm. This takes place without ever creating a continuous open channel between the cell's exterior and interior.

Tips

To understand the mechanism of cellular channels, think about a person entering a store that has a double set of automated sliding doors. When nearing the first set of automated doors, the doors open. When the person steps onto the mat between the sets of doors, the doors behind them close, trapping them in the vestibule. When they move forward, the second set of doors opens, enabling them to enter the store.

As in the case of simple or carrier-mediated diffusion, no ATP is expended in facilitated diffusion: The molecules simply move from an area of higher concentration to one of lower concentration. However, once the carrier proteins are saturated, the rate of transport cannot increase, regardless of further increases in the concentration gradient. Facilitated diffusion may occur in either direction across a plasma membrane.

All cells move glucose across their membranes through facilitated diffusion. However, several different carrier proteins are involved. In muscle cells, fat cells, and many other types of cells, the glucose transporter functions only when stimulated by the hormone *insulin*. Inadequate production of this hormone is one cause of *diabetes mellitus*, a metabolic disorder characterized by a high blood glucose level, which we discuss in Chapter 18.

Active Transport

In **active transport**, a high-energy bond (in ATP or another high-energy compound) provides the energy needed to move ions or molecules across the membrane. Despite the energy cost, active transport offers one great advantage: It does not depend on a concentration gradient. As a result, the cell can import or export specific substrates, *regardless of their intracellular or extracellular concentrations*.

All cells have carrier proteins called **ion pumps**, which actively transport the cations sodium (Na^+), potassium (K^+),

calcium (Ca^{2+}), and magnesium (Mg^{2+}) across their plasma membranes. Specialized cells can transport additional ions, such as iodide (I^-), chloride (Cl^-), and iron (Fe^{2+}).

Many of these carrier proteins move a specific cation or anion in one direction only, either into or out of the cell. Sometimes one carrier protein will move more than one kind of ion at the same time. If a countertransport, or antiport, mechanism occurs, the carrier protein (antiporter) is called an **exchange pump**.

There are two main types of active transport, primary and secondary.

Primary Active Transport: The Sodium–Potassium Exchange Pump. Primary active transport is the process of pumping solutes against a concentration gradient using the energy from ATP. One type of primary active transport involves sodium and potassium ions, which are the main cations in body fluids. The sodium ion concentration is high in the extracellular fluid, but low in the cytoplasm. The distribution of potassium ions in the body is just the opposite: low in the extracellular fluid and high in the cytoplasm. Because of leak channels in plasma membranes, sodium ions slowly diffuse into the cell, and potassium ions diffuse out. Homeostasis within the cell depends on removing sodium ions and recapturing lost potassium ions. This exchange takes place by a **sodium–potassium exchange pump**. The carrier protein involved in the process is called *sodium–potassium ATPase*.

The sodium–potassium exchange pump exchanges intracellular sodium ions for extracellular potassium ions (Figure 3–19). On average, for each ATP molecule hydrolyzed to ADP and P_i (inorganic phosphate), three sodium ions are ejected and the cell reclaims two potassium ions. If ATP is readily available, the rate of transport depends on the concentration of sodium ions in the cytoplasm. When the concentration rises, the pump becomes more active. The energy demands are impressive: Sodium–potassium ATPase may use up to 40% of the ATP produced by a resting cell!

Secondary Active Transport. In secondary active transport, the transport mechanism itself does not require energy from ATP, but the cell often needs to expend ATP later to preserve homeostasis. As with facilitated diffusion, a secondary active transport mechanism moves a specific substrate down its concentration gradient. Unlike the carrier proteins in facilitated diffusion, however, these carrier proteins can also move another substrate at the same time, without regard to its concentration gradient. In effect, the concentration gradient for one substance provides the driving force needed by the carrier protein, and the second substance gets a “free ride.”

The concentration gradient for sodium ions most often provides the driving force for symport mechanisms that move two different materials into the cell in the same direction. For

Figure 3–19 The Sodium–Potassium Exchange Pump.

The operation of the sodium–potassium exchange pump is an example of active transport. For each ATP converted to ADP, this carrier protein pump, also called sodium–potassium ATPase, carries three Na^+ out of the cell and two K^+ into the cell.

What provides the energy for the sodium–potassium exchange pump?

example, sodium-linked cotransport is important in the absorption of glucose and amino acids along the intestinal tract. The initial transport activity proceeds without direct energy expenditure, but the cell must then expend ATP to pump the arriving sodium ions out of the cell using the sodium–potassium exchange pump (Figure 3–20).

Sodium ions are also involved with many antiport mechanisms. For example, sodium–calcium countertransport keeps the intracellular calcium ion concentration very low.

Vesicular Transport

In **vesicular transport**, the traffic of materials into or out of the cell takes place in **vesicles**, small membranous sacs that form at, or fuse with, the plasma membrane. Because these vesicles move tiny droplets of fluid and solutes rather than single molecules, this process is also known as *bulk transport*. The two major types of vesicular transport are *endocytosis* and *exocytosis*.

Endocytosis

We saw earlier in this chapter that extracellular materials can be packaged in vesicles at the cell surface and imported into the cell. This process, called **endocytosis**, involves relatively

Figure 3–20 Secondary Active Transport. In secondary active transport, glucose transport by a carrier protein will take place only after the carrier has bound 2 sodium ions. In three cycles, 3 glucose molecules and 6 sodium ions are transported into the cytoplasm. The cell then pumps the sodium ions across the plasma membrane by the sodium–potassium exchange pump, at a cost of 2 ATP molecules.

large volumes of extracellular material. The three major types of endocytosis are (1) *receptor-mediated endocytosis*, (2) *pinocytosis*, and (3) *phagocytosis*. All three are active processes that require energy in the form of ATP.

The vesicles of endocytosis are generally known as *endosomes*. Their contents remain isolated from the cytoplasm, trapped within the vesicle. The enclosed materials may move into the surrounding cytoplasm by active transport, simple or facilitated diffusion, or the destruction of the vesicle membrane.

Receptor-Mediated Endocytosis. A highly selective process, **receptor-mediated endocytosis** produces vesicles that contain a specific target molecule in high concentrations. Most receptor molecules are glycoproteins, and each binds a specific ligand, or target molecule, such as a transport protein or a hormone. Cholesterol and iron ions (Fe²⁺) are too large to pass through membrane pores, but they can enter cells by receptor-mediated endocytosis.

Receptor-mediated transport begins as receptors and their ligands migrate to specialized areas of the plasma membrane called **clathrin-coated pits**. These areas of plasma membrane are inwardly depressed and are “coated” with high concentrations of the protein *clathrin* on their cytoplasmic surface. See **Figure 3–21** for an illustration and description of the complete process.

Another form of endocytosis that targets specific molecules involves receptors associated with membrane lipids and small flask-shaped indentations called **caveolae** (kav-ē-ō-lē), a term that means “little caves.” Specialized membrane proteins other than clathrin are also involved.

Pinocytosis. “Cell drinking,” or **pinocytosis** (pi-nō-sī-TŌ-sis), is the formation of *pinosomes*, endosomes filled with extracellular fluid. Most cells carry out pinocytosis. This process is not as selective as receptor-mediated endocytosis, because no receptor proteins are involved. The target appears to be the fluid contents in general, rather than specific bound ligands. In pinocytosis, a deep groove or pocket forms in the plasma membrane and then pinches off. The steps involved are similar to the steps in receptor-mediated endocytosis, except that ligand binding is not involved.

Phagocytosis. “Cell eating,” or **phagocytosis** (fag-ō-sī-TŌ-sis), produces endosomes called *phagosomes* containing solid objects that may be as large as

the cell itself. In this process, cytoplasmic extensions called **pseudopodia** (sū-dō-PŌ-dē-ah; *pseudo-*, false + *podon*, foot) surround the object, and their membranes fuse to form a phagosome. This vesicle then fuses with many lysosomes, and lysosomal enzymes digest its contents. Only specialized cells, such as macrophages, that protect tissues by engulfing bacteria, cell debris, and other abnormal materials, perform phagocytosis.

Exocytosis

Exocytosis (ek-sō-sī-TŌ-sis), noted in **Spotlight Figure 3–7** in our discussion of the Golgi apparatus, is the functional reverse of endocytosis. In exocytosis, a vesicle formed inside the cell fuses with, and becomes part of, the plasma membrane. When this takes place, the vesicle contents are released into the extracellular environment. The ejected materials may be secretory products, such as mucins or hormones, or wastes, such as those accumulating in endocytic vesicles.

Transcytosis

In a few specialized cells, endocytosis produces vesicles on one side of the cell that are discharged through exocytosis on the opposite side. This method of bulk transport is common in cells lining capillaries, which use a combination of pinocytosis and exocytosis to transfer fluid and solutes from the bloodstream into the surrounding tissues. This overall transport process is called *transcytosis* (tranz-sī-TŌ-sis).

Study **Spotlight Figure 3–22**. This figure summarizes the passive and active transport processes in cells to help you compare and contrast them.

3-7 The membrane potential of a cell results from the unequal distribution of positive and negative charges across the plasma membrane

Learning Outcome Explain the origin and significance of the cell membrane potential.

Recall that the cytoplasm-facing surface of a cell's plasma membrane has a slight negative charge with respect to the membrane's extracellular surface. (Keep in mind that this

difference in charge occurs only at the plasma membrane. The electrical charge within the cytoplasm itself is neutral when compared to the extracellular fluid.) The slight excess of positive charges on the exterior of the plasma membrane is due to cations, namely sodium. The negative charge along the cytoplasmic side of the plasma membrane is due to negatively charged protein anions that are too large to pass through any membrane ion channels. A membrane's unequal charge distribution is created by differences in the permeability of the membrane to various ions, as well as by active transport mechanisms.

The positive and negative charges are attracted to each other and would normally rush together, but the plasma membrane keeps them apart. When positive and negative charges are held apart, a **potential difference** exists between them. *Potential* refers to the energy contained by something relative to its position with something else. For example, the water behind a dam has *potential energy*—stored energy that can be released to do work. We refer to the potential difference across a plasma membrane as the **membrane potential**.

The unit of measurement of potential difference is the *volt* (V). Most cars, for example, have 12-V batteries. The membrane potentials of cells are much smaller, typically in the vicinity of 0.07 V. Such a value is usually expressed as 70 *millivolts* (mV), or thousandths of a volt.

Passive Processes

No cellular energy expended

Diffusion

Diffusion is the movement of molecules from an area of higher concentration to an area of lower concentration. That is, the movement occurs down a concentration gradient (high to low).

Factors Affecting Rate: Size of gradient, molecular size, electric charge, lipid solubility, temperature, and the presence of membrane channel proteins

Substances Involved: Gases, small inorganic ions and molecules, lipid-soluble materials

Example:

When the concentration of CO_2 inside a cell is greater than outside the cell, the CO_2 diffuses out of the cell and into the extracellular fluid.

Osmosis

Osmosis is the diffusion of water molecules across a selectively permeable membrane. Movement occurs toward higher solute concentration because that is where the concentration of water is lower. Osmosis continues until the concentration gradient is eliminated.

Factors Affecting Rate: Concentration gradient; opposing pressure

Substances Involved: Water only

Example:

If the solute concentration outside a cell is greater than inside the cell, water molecules will move across the plasma membrane into the extracellular fluid.

Facilitated diffusion

Facilitated diffusion is the movement of materials across a membrane by a carrier protein. Movement follows the concentration gradient.

Factors Affecting Rate: Concentration gradient, availability of carrier proteins

Substances Involved: Simple sugars and amino acids

Example:

Nutrients, such as glucose, that are insoluble in lipids and too large to fit through membrane channels may be transported across the plasma membrane by carrier proteins. Many carrier proteins move a specific substance in one direction only, either into or out of the cell.

Active Processes

Require ATP

Active transport

Active transport requires carrier proteins that move specific substances across a membrane against their concentration gradient. If the carrier moves one solute in one direction and another solute in the opposite direction, it is called an **exchange pump**.

Factors Affecting Rate: Availability of carrier protein, substrate, and ATP

Substances Involved: Na^+ , K^+ , Ca^{2+} , Mg^{2+} ; other solutes in special cases

Example:

The **sodium-potassium exchange pump**. One ATP molecule is hydrolyzed to ADP for each 3 sodium ions that are ejected from the cell, while 2 potassium ions are reclaimed.

Endocytosis Endocytosis is the packaging of extracellular materials into a vesicle for transport into the cell.

Receptor-Mediated Endocytosis

Example:

Cholesterol and iron ions are transported this way.

In **receptor-mediated endocytosis**, target molecules called ligands bind to receptor proteins on the membrane surface, triggering vesicle formation.

Factors Affecting Rate: Number of receptors on the plasma membrane and the concentration of ligands

Substances Involved: Ligands

Pinocytosis

In **pinocytosis**, vesicles form at the plasma membrane and bring fluids and small molecules into the cell. This process is often called “cell drinking.”

Example:

Once the vesicle is inside the cytoplasm, water and small molecules enter the cell across the vesicle membrane.

Factors Affecting Rate: Stimulus and mechanism not understood

Substances Involved: Extracellular fluid, with dissolved molecules such as nutrients

Phagocytosis

In **phagocytosis**, vesicles called phagosomes form at the plasma membrane to bring particles into the cell. This process is often called “cell eating.”

Factors Affecting Rate: Presence of pathogens and cellular debris

Substances Involved: Bacteria, viruses, cellular debris, and other foreign material

Example:

Large particles are brought into the cell by cytoplasmic extensions (called **pseudopodia**) that engulf the particle and pull it into the cell.

Exocytosis

In **exocytosis**, intracellular vesicles fuse with the plasma membrane to release fluids and/or solids from the cells.

Factors Affecting Rate: Stimulus and mechanism incompletely understood

Substances Involved: Fluid and cellular wastes; secretory products from some cells

Example:

Cellular wastes in vesicles are ejected from the cell.

The membrane potential in an unstimulated, or undisturbed, cell is called the **resting membrane potential**. Each type of cell has a characteristic resting membrane potential between -10 mV and -100 mV, with the minus sign signifying that the cytoplasmic surface of the plasma membrane has an excess of negative charges compared with the outside. Examples include fat cells (-40 mV), thyroid cells (-50 mV), neurons (-70 mV), skeletal muscle cells (-85 mV), and cardiac muscle cells (-90 mV).

If the cell's lipid barrier were removed, the positive and negative charges would rush together and the potential difference would be eliminated. Instead, the plasma membrane acts like a dam across a stream. Just as a dam resists the water pressure that builds up on the upstream side, a plasma membrane resists electrochemical forces that would otherwise drive ions into or out of the cell. So, like water behind a dam, the ions held on either side of the plasma membrane have potential energy. People have designed many ways to use the potential energy stored behind a dam—for example, turning a mill wheel or a turbine. Similarly, cells have ways of using the potential energy stored in the membrane potential. For example, changes in the membrane potential make possible the transmission of information in the nervous system, and thus our perceptions and thoughts. As described in later chapters, changes in the membrane potential also trigger the contractions of muscles and the secretions of glands.

✓ Checkpoint

27. What is the membrane potential of a cell, and in what units is it expressed?
28. If the plasma membrane of a cell were freely permeable to sodium ions (Na^+), how would the membrane potential be affected?

See the blue Answers tab at the back of the book.

3-8 Stages of the cell life cycle include interphase, mitosis, and cytokinesis

Learning Outcome Describe the stages of the cell life cycle, including interphase, mitosis, and cytokinesis, and explain their significance.

The period between fertilization and physical maturity involves tremendous changes in organization and complexity. At fertilization, a single cell is all there is, but at maturity, the body has nearly 40 trillion cells. This transformation involves a form of cellular reproduction called **cell division**. A single cell divides to produce a pair of **daughter cells**, each half the size of the original. Before dividing, each daughter cell grows to the size of the original cell.

Even when development is complete, cell division continues to be essential to survival. Cells are highly adaptable, but physical wear and tear, toxic chemicals, temperature changes,

and other environmental stresses can damage them. And, like individuals, cells age. The life span of a cell varies from hours to decades, depending on the type of cell and the stresses involved. Many cells apparently self-destruct after a certain period of time because specific “suicide genes” in the nucleus are activated. This genetically controlled death of cells is called **apoptosis** (ap-op-TŌ-sis; *apo-*, separated from + *ptosis*, a falling). Researchers have identified several genes involved in the regulation of this process. For example, a gene called *bcl-2* encodes a regulator protein that appears to prevent apoptosis and to keep a cell alive and functional. If something interferes with the function of this gene, the cell self-destructs. Silencing such genes is a strategy used to make cancer cells more vulnerable to chemotherapy.

Because a typical cell does not live nearly as long as a typical person, cell populations must be maintained over time by cell division. For cell division to be successful, the genetic material in the nucleus must be duplicated accurately, and one copy must be distributed to each daughter cell. The duplication of the cell's genetic material is called **DNA replication**, and nuclear division is called **mitosis** (mī-TŌ-sis). Mitosis occurs during the division of somatic cells. The production of sex cells involves a different process, **meiosis** (mī-Ō-sis), described in Chapter 28.

The Cell Life Cycle

Spotlight Figure 3-23 depicts the life cycle of a typical cell. That life cycle consists of an **interphase** (which includes DNA replication) of variable duration alternating with a brief period of **M phase** (which includes mitosis).

Interphase and DNA Replication

In a cell preparing to divide, interphase can be divided into the G_1 , S, and G_2 phases. DNA replication takes place during the S phase.

Interphase. **Interphase** is the stage of the cell life cycle between mitotic divisions. Somatic cells spend most of their lives in interphase. During this time, they perform all their normal functions. An interphase cell in a nondividing state is said to be in the G_0 phase. Cells of different tissues vary in the amount of time spent in the G_0 phase. Interphase cells preparing to divide exit the G_0 phase and move on to the G_1 , S, and G_2 phases.

The Process of DNA Replication. Recall that each DNA molecule consists of a pair of DNA strands joined by hydrogen bonds between complementary nitrogenous bases. Duplication of DNA, or **DNA replication**, begins when enzymes called *helicases* unwind the strands and disrupt the weak hydrogen bonds between the bases. As the strands unwind, molecules of the enzyme **DNA polymerase** bind to the exposed nitrogenous bases. This enzyme (1) promotes bonding between the nitroge-

nous bases of the DNA strand and complementary DNA nucleotides in the nucleoplasm and (2) links the nucleotides by covalent bonds. **Spotlight Figure 3–24** diagrams DNA replication.

M Phase

The M phase includes mitosis and cytokinesis. Mitosis refers to nuclear division and *cytokinesis* refers to cytoplasmic division.

Mitosis. **Mitosis** is the duplication of chromosomes in the nucleus and their separation into two identical sets in the process of somatic cell division. Although we describe mitosis in stages called *prophase*, *metaphase*, *anaphase*, and *telophase*, it is really one continuous process. See **Spotlight Figure 3–23** for a description of this process.

Tips

To remember the correct sequence of events during mitosis, imagine the U-shaped contour rug surrounding a toilet as the P-MAT, for **p**rophase, **m**etaphase, **a**naphase, and **t**elophase.

Cytokinesis. **Cytokinesis** is the division of the cytoplasm during mitosis. This process usually begins in late anaphase and continues throughout telophase, producing two daughter cells. The completion of cytokinesis marks the end of cell division, creating two separate and complete cells, each surrounded by its own plasma membrane.

The Mitotic Rate and Energy Use

The preparations for cell division that take place between the G₁ and M phases are difficult to recognize in a light micrograph. However, the start of mitosis is easy to recognize because the chromatin condenses to form highly visible chromosomes. The frequency of cell division in a tissue can be estimated by the number of cells in mitosis at any time. As a result, we often use the term **mitotic rate** when we discuss rates of cell division. In general, the longer the life expectancy of a cell type, the slower the mitotic rate. Long-lived cells, such as muscle cells and neurons, either never divide or do so only under special circumstances. Other cells, such as those covering the surface of the skin or the lining of the digestive tract, are exposed to chemicals, pathogens, and abrasion. They survive for only days or even hours. Special cells called **stem cells** maintain these cell populations through repeated cycles of cell division.

Stem cells are relatively unspecialized. Their only function is to produce daughter cells. Each time a stem cell divides, one of its daughter cells develops functional specializations while the other prepares for further stem cell divisions. The rate of stem cell division can vary with the type of tissue and the demand for new cells. In heavily abraded skin, stem cells may

divide more than once a day, but stem cells in adult connective tissues may remain inactive for years.

Dividing cells use an unusually large amount of energy. For example, they must synthesize new organic materials and move organelles and chromosomes within the cell. All these processes require ATP in substantial amounts. Cells that do not have adequate energy sources cannot divide. In a person who is starving, normal cell growth and maintenance grind to a halt. For this reason, prolonged starvation stunts childhood growth, slows wound healing, lowers resistance to disease, thins the skin, and changes the lining of the digestive tract.

Checkpoint

29. Give the biological terms for (a) cellular reproduction and (b) cellular death.
30. What enzymes must be present for DNA replication to proceed normally?
31. Describe interphase and identify its stages.
32. A cell is actively manufacturing enough organelles to serve two functional cells. This cell is probably in what phase of its life cycle?
33. Define mitosis and list its four stages.
34. What would happen if spindle fibers failed to form in a cell during mitosis?

See the blue Answers tab at the back of the book.

Tips

When considering the relative length of time that a cell spends in interphase compared to mitosis, think about an upcoming test. Preparation takes a long time (interphase) for something that happens quickly (mitosis).

3-9 Several factors regulate the cell life cycle

Learning Outcome Discuss the regulation of the cell life cycle.

In normal adult tissues, the rate of cell division balances the rate of cell loss or destruction. Mitotic rates are genetically controlled, and many different stimuli may be responsible for activating genes that promote cell division. Some of the stimuli are internal, and many cells set their own pace of mitosis and cell division.

An important internal trigger is the level of **M-phase promoting factor (MPF)**, also known as *maturation-promoting factor*. MPF is assembled from two parts: a cell division cycle protein called *Cdc2* and a second protein called *cyclin*. The cyclin level climbs as the cell life cycle proceeds. When the level is high enough, MPF appears in the cytoplasm and mitosis gets under way.

INTERPHASE

Most cells spend only a small part of their time actively engaged in cell division. Somatic cells spend the majority of their functional lives in a state known as **interphase**. During interphase, a cell performs all its normal functions and, if necessary, prepares for cell division.

A cell that is ready to divide first enters the **G₁** phase. In this phase, the cell makes enough mitochondria, cytoskeletal elements, endoplasmic reticula, ribosomes, Golgi apparatus membranes, and cytosol for two functional cells. Centriole replication begins in G₁ and commonly continues until G₂. In cells dividing at top speed, G₁ may last just 8–12 hours. Such cells use all their energy on mitosis, and all other activities cease. When G₁ lasts for days, weeks, or months, preparation for mitosis occurs as the cells perform their normal functions.

When the activities of **G₁** have been completed, the cell enters the **S phase**. Over the next 6–8 hours, the cell duplicates its chromosomes. This involves DNA replication and the synthesis of histones and other proteins in the nucleus.

Once DNA replication has ended, there is a brief (2–5-hour) **G₂ phase** devoted to last-minute protein synthesis and to the completion of centriole replication.

Centrioles in centrosome

Nucleus

Interphase

During interphase, the DNA strands are loosely coiled as chromatin and chromosomes cannot be seen.

An interphase cell in the **G₀ phase** is not preparing for division, but is performing all of the other functions appropriate for that particular cell type. Some mature cells, such as skeletal muscle cells and most neurons, remain in G₀ indefinitely and never divide. In contrast, stem cells, which divide repeatedly with very brief interphase periods, never enter G₀.

A dividing cell held in place by a holding pipette to the left and being injected with a needle from the right.

MITOSIS AND CYTOKINESIS

The M phase of the cell cycle includes mitosis and cytokinesis. Mitosis separates the duplicated chromosomes of a cell into two identical nuclei. The term **mitosis** specifically refers to the division and duplication of the cell's nucleus; division of the cytoplasm to form two distinct new cells involves a separate but related process known as **cytokinesis**.

The two daughter chromosomes are pulled apart and toward opposite ends of the cell along the **spindle apparatus** (the complex of spindle fibers).

Early prophase

Prophase (PRŌ-fāz; *pro-*, before) begins when the chromatin condenses and chromosomes become visible as single structures under a light microscope. An array of microtubules called **spindle fibers** extends between the centriole pairs. Smaller microtubules called **astral rays** radiate into the cytoplasm.

Late prophase

As a result of DNA replication during the S phase, two copies of each chromosome now exist. Each copy, called a **chromatid** (KRŌ-ma-tid), is connected to its duplicate copy at a single point, the **centromere** (SEN-trō-mēr). **Kinetochores** (ki-NĒ-tō-korz) are the protein-bound areas of the centromere; they attach to spindle fibers forming **chromosomal microtubules**.

Metaphase

Metaphase (MET-a-fāz; *meta-*, after) begins as the chromatids move to a narrow central zone called the metaphase plate. Metaphase ends when all the chromatids are aligned in the plane of the metaphase plate.

Anaphase

Anaphase (AN-a-fāz; *ana-*, apart) begins when the centromere of each chromatid pair splits and the chromatids separate. The two **daughter chromosomes** are now pulled toward opposite ends of the cell along the chromosomal microtubules.

Telophase

During telophase (TĒL-ō-fāz; *tele-*, end), each new cell prepares to return to the interphase state. The nuclear membranes re-form, the nuclei enlarge, and the chromosomes gradually uncoil. This stage marks the end of mitosis.

Cytokinesis

Cytokinesis is the division of the cytoplasm into two daughter cells. Cytokinesis usually begins with the formation of a **cleavage furrow** and continues throughout telophase. The completion of cytokinesis marks the end of cell division.

For cell division to be successful, the genetic material in the nucleus must be duplicated accurately, and one copy must be distributed to each daughter cell. This duplication of the cell's genetic material is called **DNA replication**.

Various natural body substances, such as hormones, peptides, or nutrients, derived from food can stimulate the division of specific types of cells. These substances are known as **growth factors**. Table 3–2 lists some of these chemical factors and their target tissues. We discuss them in later chapters.

Researchers have identified genes that inhibit cell division. Such genes are known as *repressor genes*. One gene, named *TP53*, encodes a protein called *p53* that binds to DNA in the nucleus. The binding, in turn, activates another gene that directs the production of growth-inhibiting factors inside the cell. Approximately half of all cancers are associated with abnormal forms of the *p53* gene.

There are indications that in humans, the *number* of cell divisions that a cell and its descendants undergo is regulated at the chromosome level by structures called **telomeres**. Telomeres are terminal segments of DNA with associated proteins. These DNA–protein complexes bend and fold repeatedly to form caps at the ends of chromosomes, much like the plastic sheaths on the tips of shoestrings. Telomeres have several functions, notably to attach chromosomes to the nuclear matrix and to protect the ends of the chromosomes from damage during mitosis. The telomeres themselves, however, are subject to wear and tear over the years. Each time a cell divides during adult life, some of the repeating segments break off, and the telomeres get shorter. When they get too short, repressor gene activity signals the cell to stop dividing.

Checkpoint

35. Define growth factor and identify several growth factors that affect cell division.

See the blue Answers tab at the back of the book.

3-10 Abnormal cell growth and division characterize tumors and cancers

Learning Outcome Discuss the relationship between cell division and cancer.

When the rates of cell division and growth exceed the rate of cell death, a tissue begins to enlarge. A **tumor**, or *neoplasm*, is a mass or swelling produced by abnormal cell growth and division. In a *benign tumor*, the cells usually remain within the tissue where it originated. Such a tumor seldom threatens an individual's life and can usually be surgically removed if its size or position disturbs tissue function. Cells in a **malignant tumor** no longer respond to normal controls. These cells do not remain confined within the epithelium or a connective tissue capsule but spread into surrounding tissues. The tumor of origin is called the *primary tumor*, and the spreading process is called **invasion**. Malignant cells may also travel to distant tissues and organs and establish *secondary tumors*.

Cancer is an illness that results from the abnormal proliferation of any of the cells in the body. It is characterized by mutations that disrupt normal cell regulatory controls and produce potentially malignant cells. Normal cells begin the path to becoming malignant when a mutation occurs in a gene involved with cell growth, differentiation, or division. The modified genes are called **oncogenes** (ON-kō-gēnz; *oncos*, tumor).

Agents that cause a mutation (a change in DNA) are called **mutagens**. Cancer-causing agents, which include many mutagens, are known as **carcinogens**. Examples of carcinogens include radiation, chemicals, bacteria, and viruses. Some chemical carcinogens, such as alcohol and estrogen, are not

Table 3–2 Chemical Factors Affecting Cell Division

Factor	Sources	Effects	Targets
M-phase promoting factor (maturation-promoting factor) (MPF)	Forms within cytoplasm from Cdc2 and cyclin	Initiates mitosis	Regulatory mechanism active in all dividing cells
Growth hormone	Anterior lobe of the pituitary gland	Stimulation of growth, cell division, differentiation	All cells, especially in epithelial and connective tissues
Prolactin	Anterior lobe of the pituitary gland	Stimulation of cell growth, division, development	Gland and duct cells of mammary glands
Nerve growth factor (NGF)	Salivary glands; other sources suspected	Stimulation of nerve cell repair and development	Neurons and neuroglia
Epidermal growth factor (EGF)	Duodenal glands; other sources suspected	Stimulation of stem cell divisions and epithelial repairs	Epidermis
Fibroblast growth factor (FGF)	Wide range of cells	Division and differentiation of fibroblasts and related cells	Connective tissues
Erythropoietin (EPO)	Kidneys (primary source)	Stimulation of stem cell divisions and maturation of red blood cells	Red bone marrow
Thymosins and related compounds	Thymus	Stimulation of division and differentiation of lymphocytes (especially T cells)	Thymus and other lymphoid tissues and organs
Chalones	Many tissues	Inhibition of cell division	Cells in the immediate area

Figure 3–25 The Development and Metastasis of Cancer.

directly mutagenic. Instead, they promote cancer by promoting rapid cell divisions, which increase the chances that a mutation will occur.

Normal cells become malignant in a multistep process. For example, a mutation may occur in one cell, which is passed on to its daughter cells. One of those cells may undergo another mutation that speeds its rate of cell division. Further growth-promoting mutations in one of those cells and its proliferating descendants may produce a primary tumor. The tumor now contains descendants of the original abnormal cell that have been selected for rapid growth. While these tumor cells are ultimately all descended from one abnormal cell, they are not identical to it due to their accumulated mutations.

Cancer cells do not resemble normal cells. They have a different shape and typically become abnormally larger or smaller. Malignant tumor cells are also less subject to controls limiting their adhesion and movement between adjacent cells and extracellular tissues. At first, the growth of the primary tumor distorts the tissue, but the basic tissue organization remains intact. **Metastasis** (me-TAS-ta-sis; *meta-*, after + *stasis*, standing still), or the spread of the cancer to other areas, begins with invasion as malignant cells “break out” of the primary tumor and invade the surrounding tissue. They may then enter the lymphatic system and accumulate in nearby lymph nodes. When metastasis involves the penetration of blood vessels, the cancer cells circulate throughout the body. Metastatic cancer progresses in the steps diagrammed in **Figure 3–25**.

+ Clinical Note Telomerase, Aging, and Cancer

Each telomere contains a sequence of about 8000 nitrogenous bases, but they are multiple copies of the same six-base sequence, TTAGGG, repeated over and over again. Telomeres are not formed by DNA polymerase. Instead, they are created by the enzyme *telomerase*. Telomerase is functional early in life, but by adulthood it becomes inactive. As a result, the telomere segments lost during each mitotic division are not replaced. Eventually, the telomeres become so short that the cell no longer divides.

This mechanism is a factor in the aging process since many of the signs of age result from the gradual loss of functional stem cell populations. Experiments are in progress to determine whether activating telomerase (or a suspected alternative repair enzyme) can forestall or reverse the effects of aging. This would seem to be a very promising area of

research. In fact, the 2009 Nobel Prize in Physiology or Medicine was awarded for telomerase research. Activate telomerase, and halt aging—sounds good, doesn’t it? Unfortunately, there’s a catch: In adults, telomerase activation is a key step in the development of cancer.

If for some reason a cell with short telomeres does *not* respond normally to repressor genes, it continues to divide. The result is mechanical damage to the DNA strands, chromosomal abnormalities, and mutations. Interestingly, one of the first consequences of such damage is the abnormal activation of telomerase. Once this occurs, the abnormal cells can continue dividing indefinitely. Telomerase is active in at least 90% of all cancer cells. Research is under way to find out how to turn off telomerase that has been improperly activated.

Clinical Note Breakthroughs with Stem Cells

In most cases, cell differentiation is irreversible. Once genes are turned off, they won't be turned back on. However, some cells, such as stem cells, are relatively undifferentiated. These cells can differentiate into any of several different cell types, depending on local conditions. For example, if nutrients are abundant, stem cells can differentiate into fat cells. Researchers are gradually discovering what chemical cues and genes control the differentiation of specific cell types. Such research has resulted in the ability to "turn back the clock" in some types of adult somatic cells and reprogram them into a form of stem cell called *induced pluripotent stem (iPS) cells*. The ability to take a person's stem cells or somatic cells and create new cells or neurons to treat disease may one day revolutionize the practice of medicine.

Parkinson's Disease (PD) is a neurodegenerative disease characterized by progressive degeneration and loss of dopamine-producing neurons. (Dopamine is one kind of *neurotransmitter*, a substance that one neuron releases to communicate with other neurons.) PD may be the first disorder suited to treatment by implanting stem cells. Several laboratories have induced either iPS cells or *embryonic stem cells* to differentiate into cells that function as dopamine-producing neurons. In rodent studies, both iPS and embryonic stem cell-derived dopamine neurons re-innervated the brains of rats with Parkinson's disease. These cells also released dopamine and improved motor function.

3

Responding to cues that are unknown, cancer cells in the bloodstream ultimately escape out of blood vessels to establish secondary tumors at other sites. The cancer cells in these tumors are extremely active metabolically, and their presence stimulates the growth of new blood vessels (*angiogenesis*) into the area. The increased blood supply provides additional nutrients to the cancer cells and further accelerates tumor growth and metastasis.

As malignant tumors grow, organ function begins to deteriorate. The malignant cells may no longer perform their original functions, or they may perform normal functions in an abnormal way. For example, endocrine cancer cells may produce normal hormones, but in excessively large amounts.

Cancer cells do not use energy very efficiently. They grow and multiply at the expense of healthy tissues, competing for space and nutrients with normal cells. This competition contributes to the starved appearance of many patients in the late stages of cancer. Death may result from the compression of vital organs when nonfunctional cancer cells have killed or replaced the healthy cells in those organs, or when the cancer cells have starved normal tissues of essential nutrients. We discuss cancer further in later chapters that deal with specific systems.

Checkpoint

36. An illness characterized by mutations that disrupt normal control mechanisms and produce potentially malignant cells is termed ____.
37. Define metastasis.

See the blue Answers tab at the back of the book.

3-11 Cellular differentiation is cellular specialization as a result of gene activation or repression

Learning Outcome Define cellular differentiation and explain its importance.

An individual's liver cells, fat cells, and neurons all contain the same chromosomes and genes, but in each case a different set of genes has been turned *off*. In other words, liver cells and fat cells differ because liver cells have one set of genes accessible for transcription, or activation, and fat cells have another.

When a gene is functionally eliminated, the cell loses the ability to produce a particular protein—and to perform any functions involving that protein. Each time another gene switches off, the cell's functional abilities become more restricted. This development of specific cellular characteristics and functions that are different from the original cell is called **cellular differentiation**.

Fertilization produces a single cell with all its genetic potential intact. Repeated cell divisions follow, and cellular differentiation begins as the number of cells increases. Cellular differentiation produces specialized cells with limited capabilities. These cells form organized collections known as *tissues*, each with discrete functional roles. In Chapter 4, we examine the structure and function of tissues and consider the role of tissue interactions in maintaining homeostasis.

Checkpoint

38. Define cellular differentiation.

See the blue Answers tab at the back of the book.

3 Chapter Review

Study Outline

An Introduction to Cells

1. Contemporary *cell theory* incorporates several basic concepts: (1) Cells are the building blocks of all plants and animals; (2) cells are produced by the division of preexisting cells; (3) cells are the smallest units that perform all vital physiological functions; and (4) each cell maintains homeostasis at the cellular level. (*Spotlight Figure 3–1*)
2. **Cytology**, the study of cellular structure and function, is part of **cell biology**.
3. The human body contains two types of cells: **sex cells** (*sperm* and *oocytes*) and **somatic cells** (all other cells). (*Spotlight Figure 3–1*)

3-1 The plasma membrane separates the cell from its surrounding environment and performs various functions

4. A typical cell is surrounded by **extracellular fluid**—specifically, the **interstitial fluid** of the tissue. The cell's outer boundary is the **plasma membrane (cell membrane)**.
5. The plasma membrane's functions include physical isolation, regulation of exchange with the environment, sensitivity to the environment, and structural support. (*Figure 3–2*)
6. The plasma membrane is a **phospholipid bilayer**, which contains other lipids, proteins, and carbohydrates.
7. **Integral proteins** are part of the membrane itself; **peripheral proteins** are attached to, but can separate from, the membrane.
8. Membrane proteins can act as anchors (**anchoring proteins**), identifiers (**recognition proteins**), enzymes, receptors (**receptor proteins**), carriers (**carrier proteins**), or **channels**.
9. The carbohydrate portions of *proteoglycans*, *glycoproteins*, and *glycolipids* form the **glycocalyx** on the outer cell surface. Functions include lubrication and protection, anchoring and locomotion, specificity in binding, and recognition.

3-2 Organelles within the cytoplasm perform particular functions

10. The **cytoplasm** contains the fluid **cytosol** and the **organelles** suspended in the cytosol.
11. Cytosol (intracellular fluid) differs from extracellular fluid in composition and in the presence of **inclusions**.
12. **Nonmembranous organelles** are not completely enclosed by membranes, and all of their components are in direct contact with the cytosol. They include the *cytoskeleton*, *microvilli*, *centrioles*, *cilia*, *ribosomes*, and *proteasomes*. (*Spotlight Figure 3–1*)
13. **Membranous organelles** are surrounded by phospholipid membranes that isolate them from the cytosol. They include the *endoplasmic reticulum*, the *Golgi apparatus*, *lysosomes*, *peroxisomes*, *mitochondria*, and *nucleus*. (*Spotlight Figure 3–1*)
14. The **cytoskeleton** gives the cytoplasm strength and flexibility. All cells have three cytoskeletal components: **microfilaments** (typically made of **actin**), **intermediate filaments**, and **microtubules** (made of **tubulin**). Muscle cells also have *thick filaments* (made of *myosin*). (*Figure 3–3*)
15. **Microvilli** are small, nonmotile projections of the plasma membrane that increase the surface area exposed to the extracellular environment. (*Figure 3–3*)

16. The **centrosome** is a region of the cytoplasm near the nucleus. It is the microtubule organizing center surrounding the paired centrioles. **Centrioles** direct the movement of chromosomes during cell division. (*Figure 3–4*)
17. A single, nonmotile **primary cilium** is sensitive to environmental stimuli. Multiple **motile cilia**, each anchored by a **basal body**, beat rhythmically to move fluids or secretions across the cell surface. (*Figure 3–4*)
18. **Ribosomes**, responsible for manufacturing proteins, are composed of a **small** and a **large ribosomal subunit**, both of which contain **ribosomal RNA (rRNA)**. **Free ribosomes** are in the cytoplasm, and **fixed ribosomes** are attached to the endoplasmic reticulum. (*Spotlight Figure 3–1*)
19. **Proteasomes** remove and break down damaged or abnormal proteins that have been tagged with *ubiquitin*.
20. The **endoplasmic reticulum (ER)** is a network of intracellular membranes that function in synthesis, storage, transport, and detoxification. The ER forms hollow tubes, flattened sheets, and chambers called **cisternae**. **Smooth endoplasmic reticulum (SER)** is involved in lipid synthesis; **rough endoplasmic reticulum (RER)** contains ribosomes on its outer surface and forms **transport vesicles**. (*Figure 3–5*; *Spotlight Figure 3–7*)
21. The **Golgi apparatus**, or **Golgi complex**, forms **secretory vesicles** and new plasma membrane components, and packages *lysosomes*. Secretions exit the cell by exocytosis. (*Figure 3–6*; *Spotlight Figure 3–7*)
22. **Lysosomes**, vesicles filled with digestive enzymes, are responsible for the **autolysis** of injured cells. (*Figures 3–6, 3–8*; *Spotlight Figure 3–7*)
23. **Peroxisomes** carry enzymes that neutralize potentially dangerous free radicals.
24. **Membrane flow**, or *membrane trafficking*, refers to the continuous movement and recycling of the membrane among the ER, vesicles, the Golgi apparatus, and the plasma membrane.
25. **Mitochondria** are responsible for ATP production through aerobic metabolism. The **matrix**, or fluid contents of a mitochondrion, lies inside the **cristae**, or folds of an inner membrane. (*Figure 3–9*)

3-3 The nucleus contains DNA and enzymes essential for controlling cellular activities

26. The **nucleus** is the control center of cellular operations. It is surrounded by a **nuclear envelope** (a double membrane with a **peri-nuclear space**), through which it communicates with the cytosol by way of **nuclear pores**. (*Spotlight Figure 3–1*; *Figure 3–10*)
27. The nucleus contains a supportive **nuclear matrix**; one or more **nucleoli** typically are present.
28. The nucleus controls the cell by directing the synthesis of specific proteins, using information stored in **chromosomes**,

which consist of DNA bound to **histones**. In nondividing cells, DNA and associated proteins form a tangle of filaments called **chromatin**. (Figure 3–11)

29. The cell's information storage system, the **genetic code**, is called a **triplet code** because a sequence of three nitrogenous bases specifies the identity of a single amino acid. Each **gene** contains all the DNA triplets needed to produce a specific polypeptide chain.

3-4 DNA controls protein synthesis, cell structure, and cell function

30. As **gene activation** begins, **RNA polymerase** must bind to the gene.
31. **Transcription** is the production of RNA from a DNA template. After transcription, a strand of **messenger RNA (mRNA)** carries instructions from the nucleus to the cytoplasm. (Figure 3–12)
32. During **translation**, a functional polypeptide is constructed using the information contained in the sequence of **codons** along an mRNA strand. The mRNA codons correspond to DNA triplets. The sequence of codons determines the sequence of amino acids in the polypeptide.
33. During translation, complementary base pairing of **anticodons** to mRNA codons occurs, and **transfer RNA (tRNA)** molecules bring amino acids to the ribosomal complex. Translation includes three phases: **initiation**, **elongation**, and **termination**. (Spotlight Figure 3–13; Table 3–1)
34. Through protein synthesis, the DNA of the nucleus controls the synthesis of enzymes and structural proteins that provide short- and long-term homeostatic adjustments affecting the cell's biochemical and physical characteristics.

3-5 Diffusion is a passive transport mechanism that assists membrane passage of solutes and water

35. The **permeability** of a barrier such as the plasma membrane is an indication of the barrier's effectiveness. Nothing can pass through an **impermeable** barrier; anything can pass through a **freely permeable** barrier. Plasma membranes are **selectively permeable**.
36. **Diffusion** is the net movement of a substance from an area of higher concentration to an area of lower concentration. Diffusion occurs until the **concentration gradient** is eliminated. (Figures 3–14, 3–15)
37. Most lipid-soluble materials, water, and gases freely diffuse across the phospholipid bilayer of the plasma membrane. Small water-soluble molecules and ions rely on channel-mediated diffusion through a passageway within a transmembrane protein. **Leak channels** are passive channels that allow ions across the plasma membrane.
38. **Osmosis** is the net flow of water across a selectively permeable membrane in response to differences in solute concentration. **Osmotic pressure** of a solution is the force of water movement into that solution resulting from its solute concentration. **Hydrostatic pressure** can oppose osmotic pressure. (Figure 3–16)
39. **Tonicity** describes the effects of osmotic solutions on cells. A solution that does not cause an osmotic flow is **isotonic**. A solution that causes water to flow into a cell is **hypotonic** and can lead to **hemolysis** of red blood cells. A solution that causes water to flow out of a cell is **hypertonic** and can lead to **crenation**. (Figure 3–17)

3-6 Carrier-mediated and vesicular transport assist membrane passage of specific substances

40. Carrier-mediated transport involves the binding and transporting of specific ions by integral proteins.

Symport (cotransport) moves two substances in the same direction; **antiport (countertransport)** moves them in opposite directions.

41. In **facilitated diffusion**, compounds are transported across a membrane after binding to a **receptor site** within the channel of a carrier protein. (Figure 3–18)
42. **Active transport** mechanisms consume ATP and are not dependent on concentration gradients. Some **ion pumps** are **exchange pumps**. **Secondary active transport** may involve symport (cotransport) or antiport (countertransport). (Figures 3–19, 3–20)
43. In **vesicular transport**, materials move into or out of the cell in membranous **vesicles**. Movement into the cell is accomplished through **endocytosis**, an active process that can take three forms: **receptor-mediated endocytosis** (by means of **clathrin-coated vesicles**), **pinocytosis**, or **phagocytosis** (using **pseudopodia**). The ejection of materials from the cytoplasm is accomplished by **exocytosis**. (Figure 3–21; Spotlight Figure 3–22)

3-7 The membrane potential of a cell results from the unequal distribution of positive and negative charges across the plasma membrane

44. The **potential difference**, measured in volts, between the two sides of a plasma membrane is a **membrane potential**. The membrane potential in an unstimulated, or undisturbed, cell is the cell's **resting membrane potential**.

3-8 Stages of the cell life cycle include interphase, mitosis, and cytokinesis

45. **Cell division** is the reproduction of cells. **Apoptosis** is the genetically controlled death of cells. **Mitosis** is the nuclear division of somatic cells. Sex cells are produced by **meiosis**. (Spotlight Figure 3–23)
46. Somatic cells spend most of their time in **interphase**, which includes the **G1**, **S (DNA replication)**, and **G2 phases**. (Spotlight Figures 3–23, 3–24)
47. Mitosis proceeds in four stages: **prophase**, **metaphase**, **anaphase**, and **telophase**. (Spotlight Figure 3–23)
48. During **cytokinesis**, the cytoplasm is divided to form two daughter cells and cell division ends. (Spotlight Figure 3–23)
49. In general, the longer the life expectancy of a cell type, the slower the **mitotic rate**. **Stem cells** undergo frequent mitosis to replace other, more specialized cells.

3-9 Several factors regulate the cell life cycle

50. A variety of hormones and **growth factors** can stimulate cell division and growth. (Table 3–2)

3-10 Abnormal cell growth and division characterize tumors and cancers

51. Produced by abnormal cell growth and division, a **tumor**, or **neoplasm**, can be **benign** or **malignant**. Malignant cells may spread locally (by **invasion**) or to distant tissues and organs (through **metastasis**). The resultant illness is called **cancer**. Modified genes called **oncogenes** often cause malignancy. (Figure 3–25)

3-11 Cellular differentiation is cellular specialization as a result of gene activation or repression

52. **Cellular differentiation**, a process of cellular specialization, results from the inactivation of particular genes in different cells, producing populations of cells with limited capabilities. Specialized cells form organized collections called **tissues**, each of which has certain functional roles.

Review Questions

See the blue Answers tab at the back of the book.

LEVEL 1 Reviewing Facts and Terms

1. In the following diagram, identify the type of solution (hypertonic, hypotonic, or isotonic) in which the red blood cells are immersed.

2. The process that transports solid objects such as bacteria into the cell is called (a) pinocytosis, (b) phagocytosis, (c) exocytosis, (d) receptor-mediated endocytosis, (e) channel-mediated transport.
3. Plasma membranes are made less permeable by (a) phospholipids, (b) glycolipids, (c) anchoring proteins, (d) integral proteins, (e) cholesterol.
4. _____ ion concentration is high in extracellular fluids, and _____ ion concentration is high in the cytoplasm. (a) Calcium; magnesium, (b) Chloride; sodium, (c) Potassium; sodium, (d) Sodium; potassium.
5. At resting membrane potential, the cytoplasmic side of the membrane surface of the cell is _____, and the cell extracellular membrane surface is _____. (a) slightly negative; slightly positive, (b) slightly positive; slightly negative, (c) slightly positive; neutral, (d) slightly negative; neutral.
6. The organelle responsible for the breakdown and recycling of damaged or abnormal intracellular proteins is the (a) lysosome, (b) endoplasmic reticulum, (c) Golgi apparatus, (d) proteasome.
7. The organelle essential for the modification and packaging of newly synthesized proteins is the (a) nucleus, (b) Golgi apparatus, (c) ribosome, (d) proteasome.
8. The nucleotide sequence of the anticodon for the DNA triplet TCG is (a) AGC, (b) TCG, (c) ACG, (d) UCG.
9. Ca^{2+} and Mg^{2+} ions are transported through the plasma membrane by (a) exocytosis, (b) receptor-mediated endocytosis, (c) osmosis, (d) facilitated diffusion, (e) active transport.
10. One chemical factor that stimulates stem cell division and the maturation of red blood cells is (a) growth hormone, (b) thymosin, (c) erythropoietin, (d) epidermal growth factor.
11. List the four basic concepts that make up the cell theory.
12. What are four key functions of the glycocalyx?
13. What are the primary functions of membrane proteins?
14. By what three major transport mechanisms do substances get into and out of cells?

15. List five important factors that influence diffusion rates.
16. What are the four major functions of the endoplasmic reticulum?

LEVEL 2 Reviewing Concepts

17. If you put cells in a hypotonic solution, (a) water will flow into the cells, (b) the cell membranes will become impermeable, (c) the cells will lose water by osmosis, (d) the cells will remain unchanged.
18. In humans, cells with a flagellum (a) are found in the respiratory epithelium of the nasal cavity, (b) are found in most hormone-secreting tissues, (c) are sperm, (d) are macrophages, (e) are found exclusively in the uterine tubes.
19. In receptor-mediated endocytosis, special ligands bind to membrane receptors and become enclosed in _____, which fuse with _____. (a) clathrin-coated vesicles, secondary lysosomes, (b) primary lysosomes, phagosomes, (c) clathrin-coated vesicles, primary lysosomes, (d) phagosomes, primary lysosomes.
20. Suppose that a DNA segment has the following nucleotide sequence: CTC-ATA-CGA-TTC-AAG-TTA. Which nucleotide sequences would a complementary mRNA strand have? (a) GAG-UAU-GAU-AAC-UUG-AAU, (b) GAG-TAT-GCT-AAG-TTC-AAT, (c) GAG-UAU-GCU-AAG-UUC-AAU, (d) GUG-UAU-GGA-UUG-AAC-GGU.
21. How many amino acids are coded in the DNA segment in Review Question 20? (a) 18, (b) 9, (c) 6, (d) 3.
22. The sodium-potassium exchange pump (a) is an example of facilitated diffusion, (b) does not require the input of cellular energy in the form of ATP, (c) moves the sodium and potassium ions along their concentration gradients, (d) is composed of a carrier protein located in the plasma membrane, (e) is not necessary for the maintenance of homeostasis.
23. If a cell lacked mitochondria, it would not be able to (a) divide, (b) synthesize proteins, (c) detoxify toxins, (d) produce enough energy, (e) move.
24. DNA replication is the duplication of the cell's genetic material. List, in sequence, the enzymes which are involved in this process.
25. List the stages of mitosis and briefly describe the events that occur in each.
26. a) What is apoptosis? b) By which mechanism is apoptosis induced?

LEVEL 3 Critical Thinking and Clinical Applications

27. The transport of iron ions through the cell membrane is characterized by (1) receptor proteins on the cell surface; (2) iron ion-filled vesicles fusing with lysosomes in the cytosol; and (3) iron ions being removed from the secondary lysosomes and absorbed into the cytoplasm. What type of transport is this?
28. Solution A has a higher solute concentration than solution B. The solutions are separated by a selectively permeable barrier. What can you do to keep fluid levels in the two solutions equal?
29. Which cellular process is impossible in the absence of microtubules? (a) removal of damaged or denatured proteins, (b) anchoring the position of major organelles, (c) movement of molecules in and out of the cell, (d) attachment of the plasma membrane to the cytoplasm, (e) packaging of special enzymes within vesicles.
30. What is the benefit of having some of the cellular organelles enclosed by a membrane similar to the plasma membrane?

CLINICAL CASE Wrap-Up Mohan Gets the Runs

The stool sample test confirmed what the doctor had suspected; Mohan was infected with *Vibrio cholerae*, the bacterium which causes cholera. Cholera is a common disease in Africa, Southeast Asia, and Latin America and is associated with poor sanitary conditions. Mohan most likely acquired the infection from drinking contaminated water when he was away on his trip.

The main characteristic of cholera is fluid and electrolyte loss caused by the severe watery diarrhea and vomiting. This leads to dehydration and electrolyte imbalances which can prove fatal if not treated. Mohan's symptoms of thirst, lack of skin elasticity, dry mouth, and low blood pressure all indicate that he was very dehydrated.

V. cholerae infection causes diarrhea and fluid loss because the bacterium produces a toxin which greatly increases the

ATP-mediated transport of Cl^- from enterocytes (the cells surrounding the intestine) into the intestinal lumen. Other electrolytes such as Na^+ and K^+ and water will then follow the chloride ions, resulting in an excessive loss of water and electrolytes into the intestinal lumen and the watery diarrhea characteristic of cholera.

1. What advice would you give to Mohan to reduce the chances of him contracting cholera again if he goes away on another such trip?
2. Cholera can be treated successfully. What do you think would be the best strategies to use to treat a patient with cholera?

See the blue Answers tab at the back of the book.

Related Clinical Terms

anaplasia: An irreversible change in the size and shape of tissue cells.

dysplasia: A reversible change in the normal shape, size, and organization of tissue cells.

genetic engineering: A general term that encompasses attempts to change the genetic makeup of cells or organisms, including humans.

hyperplasia: An increase in the number of normal cells (not tumor formation) in a tissue or organ, thus enlarging that tissue or organ.

hypertrophy: The enlargement of an organ or tissue due to an increase in the size of its cells.

liposome: A minute spherical sac of lipid molecules enclosing a water droplet. Often formed artificially to carry drugs into the tissues.

necrosis: Death of one or more cells in an organ or tissue due to disease, injury, or inadequate blood supply.

oncologist: Physician who specializes in the identification and treatment of cancers.

prion: A protein particle that is not visible microscopically, contains no nucleic acid, is resistant to destruction, and is thought to be the cause of some brain diseases such as bovine spongiform encephalopathy (BSE), scrapie, and Creutzfeldt-Jakob disease.

scanning electron micrograph (SEM): An image produced by an electron microscope in which a beam of focused electrons moves across an object with that object producing secondary electrons that are scattered and formatted into a three-dimensional image on a cathode-ray tube—also called *scanning microscope*.

transmission electron micrograph (TEM): A cross-sectional image produced by an electron microscope that passes a beam of electrons through an extremely small specimen. After passing through the sample the electrons are focused to form a magnified sectional view.

4

The Tissue Level of Organization

Learning Outcomes

These Learning Outcomes correspond by number to this chapter's sections and indicate what you should be able to do after completing the chapter.

- 4-1 ■ Identify the four major types of tissues in the body and describe their roles.
- 4-2 ■ Discuss the types and functions of epithelial tissue.
- 4-3 ■ Describe the relationship between structure and function for each type of epithelium.
- 4-4 ■ List the specific functions of connective tissue and describe the three main categories of connective tissue.
- 4-5 ■ Compare the structures and functions of the various types of connective tissue proper and describe the layers of connective tissue called fascia.
- 4-6 ■ Describe the fluid connective tissues blood and lymph and explain their relationship with interstitial fluid in maintaining homeostasis.
- 4-7 ■ Describe how cartilage and bone function as supporting connective tissues.
- 4-8 ■ Explain how epithelial and connective tissues combine to form four types of tissue membranes and specify the functions of each.
- 4-9 ■ Describe the three types of muscle tissue and the special structural features of each type.
- 4-10 ■ Discuss the basic structure and role of nervous tissue.
- 4-11 ■ Describe how injuries affect the tissues of the body.
- 4-12 ■ Describe how aging affects the tissues of the body.

CLINICAL CASE Rubber Joints

All her life Anne Marie has felt “delicate.” She is a horrible athlete. She once dislocated both shoulders attempting to play high school volleyball. And she has an unstable feeling, as if her kneecaps will dislocate, when she tries dancing or any other twisting activity. She sprains an ankle at least once a year. She has always been “double jointed,” with fingers that she can bend back until they nearly touch her posterior forearm. Her elbows and knees all hyperextend, moving beyond their normal anatomical position.

Anne Marie’s skin has always been delicate, pale, and very stretchy. She seems to get abrasions and cuts easily. These heal

slowly, leaving huge scars that are also fragile. Once, she had stitches in her face and they pulled right through the skin. Now she has a wide scar over her eyebrow. She bruises easily, too.

Anne Marie thinks she is a lot like her dad. He has the same easy-bruising skin that heals poorly and seems to tear with minimal trauma. He was never very athletic and is also loose jointed. He has twisted both ankles many times. Fortunately, he has a desk job. **What is the cause of Anne Marie’s unusual physical traits?**

To find out, turn to the Clinical Case Wrap-Up at the end of the chapter.

4

An Introduction to the Tissue Level of Organization

In this chapter we discuss how a variety of cell types arranged in various combinations form *tissues*, which are structures with discrete structural and functional properties. Tissues in combination form organs, such as the heart or liver, and in turn organs can be grouped into 11 organ systems. Thus, learning about tissues will help you understand the descriptions of organs and organ systems in later chapters. It will also help you make the connections between anatomical structures and their physiological functions.

4-1 The four tissue types are epithelial, connective, muscle, and nervous

Learning Outcome Identify the four major types of tissues in the body and describe their roles.

The human body contains trillions of cells, but only about 200 *types* of cells. To work efficiently, several different types of cells must coordinate their efforts. Cells working together form **tissues**—collections of specialized cells and cell products that carry out a limited number of functions (**Figure 4-1**). The study of tissues is called **histology**. Histologists recognize the following four basic types of tissue:

- **Epithelial tissue** covers exposed surfaces, lines internal passageways and chambers, and forms glands.
- **Connective tissue** fills internal spaces, provides structural support for other tissues, transports materials within the body, and stores energy.
- **Muscle tissue** is specialized for contraction and includes the skeletal muscles of the body, the muscle of the heart, and the muscular walls of hollow organs.

- **Nervous tissue** carries information from one part of the body to another in the form of electrical impulses.

In this chapter we introduce the basic characteristics of these tissues.

Checkpoint

1. Define histology.
2. Identify the four major types of tissues in the body.

See the blue Answers tab at the back of the book.

4-2 Epithelial tissue covers body surfaces, lines internal surfaces, and serves other essential functions

Learning Outcome Discuss the types and functions of epithelial tissue.

We begin our discussion with **epithelial tissue** because it includes a very familiar feature—the surface of the skin. Epithelial tissue includes epithelia and glands. **Epithelia** (ep-i-THĒ-lē-a; singular, *epithelium*) are layers of cells that cover external or line internal surfaces. *Glands* are structures that produce fluid secretions. They are either attached to or derived from epithelia.

Epithelia cover every exposed surface of the body. Epithelia form the surface of the skin and line the digestive, respiratory, reproductive, and urinary tracts. In fact, they line all passageways that communicate with the outside world. The more delicate epithelia line internal cavities and passageways, such as the chest cavity, fluid-filled spaces in the brain, the inner surfaces of blood vessels, and the chambers of the heart.

We now discuss the functions, characteristics, and specializations of epithelial tissue and how it maintains its effectiveness as a barrier between the external environment and the body’s interior.

Figure 4–1 An Orientation to the Body's Tissues.

Functions of Epithelial Tissue

Epithelia perform the following four essential functions:

- **Provide Physical Protection.** Epithelia protect exposed and internal surfaces from abrasion, dehydration, and destruction by chemical or biological agents.
- **Control Permeability.** Any substance that enters or leaves the body must cross an epithelium. Some epithelia are relatively impermeable. Others are easily crossed by compounds as large as proteins. Many epithelia contain the molecular “machinery” needed for absorbing or secreting specific substances. The epithelial barrier can also be regulated and modified in response to stimuli. For example, hormones can affect the transport of ions and nutrients through epithelial cells. Even physical stress can alter the structure and properties of epithelia. For example, calluses form on the hands when doing repetitive tasks like shoveling dirt or raking leaves.
- **Provide Sensation.** Most epithelia are extremely sensitive to stimulation because they have a large sensory nerve supply. These sensory nerves continually provide information about the external and internal environments. For example, the lightest touch of a mosquito stimulates sensory neurons identifying the area to swat. A *neuroepithelium* is an epithelium that is specialized to perform a particular sensory function. Our neuroepithelia contain sensory cells that provide the sensations of smell, taste, sight, equilibrium, and hearing.
- **Produce Specialized Secretions.** Epithelial cells that produce secretions are called *gland cells*. Individual gland cells are usually scattered among other cell types in an epithelium. In a *glandular epithelium*, most or all epithelial cells produce secretions. These cells either discharge their secretions onto the surface of the epithelium (to provide physical protection or temperature regulation) or release them into the surrounding interstitial fluid and blood (to act as chemical messengers).

Characteristics of Epithelial Tissue

Epithelia have several important features:

- **Polarity.** An epithelium has an exposed surface, either facing the external environment or an internal space, and a base, which is attached to underlying tissues. The term **polarity** refers to the presence of structural and functional differences between the exposed and attached surfaces. An epithelium consisting of a single layer of cells has an exposed **apical surface** and an attached **basal surface**. The two surfaces differ in plasma membrane structure and function. Often, the apical surface has microvilli; sometimes it has cilia. The functional polarity is also evident in the uneven distribution of organelles between the exposed surface and the basement membrane. In some epithelia, such as the lining of the kidney tubules, mitochondria are concentrated near the base of the cell, where energy is in high demand for the cell's transport activities (**Figure 4-2**).
- **Cellularity.** Epithelia are made almost entirely of cells bound closely together by interconnections known as **cell junctions**. In other tissue types, the cells are often widely separated by extracellular materials.
- **Attachment.** The base of an epithelium is bound to a thin, noncellular **basement membrane**. This basement membrane is formed from the fusion of several successive layers (the basal lamina and reticular lamina), a collagen matrix, and proteoglycans (intercellular cement). The basement membrane adheres to the basal surface and to the underlying tissues to establish the cell's border and resist stretching.

- **Avascularity.** Epithelia are **avascular** (ā-VAS-kū-lar; *a-*, without + *vas*, vessel), which means that they lack blood vessels. Epithelial cells get nutrients by diffusion or absorption across either the exposed or the attached epithelial surface.
- **Regeneration.** Epithelial cells that are damaged or lost at the exposed surface are continuously replaced through stem cell divisions in the epithelium. Regeneration is a characteristic of other tissues as well, but the rates of cell division and replacement are typically much higher in epithelia than in other tissues.

Specializations of Epithelial Cells

How are epithelial cells different from other body cells? They have several structural specializations. For the epithelium to perform the functions just listed, individual epithelial cells may be specialized for (1) the movement of fluids over the epithelial surface, providing protection and lubrication; (2) the movement of fluids through the epithelium, to control permeability; or (3) the production of secretions that provide physical protection or act as chemical messengers.

The specialized epithelial cell is often divided into two functional regions, which means the cell has a strong polarity. One is the **apical surface**, where the cell is exposed to an internal or external environment. The other consists of the **basolateral surfaces**, which include both the base (basal surface), where the cell attaches to underlying epithelial cells or deeper tissues, and the sides (lateral surfaces), where the cell contacts its neighbors (**Figure 4-2**).

Many epithelial cells that line internal passageways have **microvilli** on their exposed surfaces. Just a few may be present, or microvilli may carpet the entire surface. Microvilli are especially abundant on epithelial surfaces where absorption and secretion take place, such as along portions of the digestive system and kidneys. The epithelial cells in these locations are transport specialists. Each cell has at least 20 times more surface area to transport substances than it would have without microvilli.

Motile cilia are characteristic of surfaces covered by a **ciliated epithelium**. A typical ciliated cell projects about 250 cilia that beat in a coordinated manner. The synchronized beating of the cilia moves substances over the epithelial surface. For example, the ciliated epithelium that lines the respiratory tract moves mucus up from the lungs and toward the throat, as though on an escalator. The sticky mucus traps inhaled particles, including dust, pollen, and pathogens. The ciliated epithelium then carries the mucus and the trapped debris to the throat. There they are swallowed or expelled by coughing. If abrasion or toxic compounds such as nicotine and carbon monoxide in cigarette smoke injure the cilia or the epithelial cells, ciliary movement can stop. Without the protective upward flow of mucus, infection or disease becomes more likely.

Figure 4-2 The Polarity of Epithelial Cells.

Maintaining the Integrity of Epithelia

To be effective as a barrier, an epithelium must form a complete cover or lining. Three factors help maintain the physical integrity of an epithelium: (1) intercellular connections, (2) attachment to the basement membrane, and (3) epithelial maintenance and repair.

4

Intercellular Connections

Cells in an epithelium are firmly attached to one another, and the epithelium as a unit is attached to extracellular fibers of the superficial basal lamina of the basement membrane. Many body cells form permanent or temporary bonds with other cells or extracellular material. Epithelial cells, however, are specialists in intercellular connection.

Intercellular connections involve either extensive areas of opposing plasma membranes or specialized attachment sites called *cell junctions*, discussed shortly. Large areas of opposing plasma membranes are interconnected by transmembrane proteins called **cell adhesion molecules** (CAMs), which bind to each other and to extracellular materials. For example, CAMs on the basolateral surface of an epithelium help bind the cell to the underlying basement membrane. The membranes of adjacent cells may also be bonded by a thin layer of proteoglycans that contain polysaccharide derivatives known as *glycosaminoglycans* (GAGs), most notably, *hyaluronan* (hyaluronic acid). Proteoglycans also help prevent water loss.

Cell junctions are specialized areas of the plasma membrane that attach a cell to another cell or to extracellular materials. The three most common types of cell junctions are (1) gap junctions, (2) tight junctions, and (3) desmosomes (**Figure 4-3a**).

Gap Junctions. Some epithelial functions require rapid intercellular communication. At a **gap junction** (**Figure 4-3b**), two cells are held together by two embedded interlocking transmembrane proteins called *connexons*. Each connexon is composed of six *connexin* proteins that form a cylinder with a central pore. Two aligned connexons form a narrow passageway that lets small molecules and ions pass from cell to cell. Gap junctions are common among epithelial cells, where the movement of ions helps coordinate functions such as the beating of cilia. Gap junctions are also common in other tissues. For example, gap junctions in cardiac muscle tissue and smooth muscle tissue are essential in coordinating muscle cell contractions. Many human diseases are caused by mutations in the genes that code for different connexin proteins.

Tight Junctions. Tight junctions encircle the apical regions of epithelial cells. At a **tight junction** (also known as an *occluding junction*), the lipid portions of the two plasma membranes are tightly bound together by interlocking membrane proteins (**Figure 4-3c**). Inferior to the tight junctions, a continuous

adhesion belt forms a band that encircles cells and binds them to adjacent cells. The bands are attached to the microfilaments of the terminal web.

Tight junctions largely prevent water and solutes from passing between the cells. When the epithelium lines a tube, such as the intestinal tract, the apical surfaces of the epithelial cells are exposed to the space inside the tube, a passageway called the **lumen** (LŪ-men). Tight junctions effectively isolate the contents of the lumen from the basolateral surfaces of the cell. For example, tight junctions near the apical surfaces of cells that line the digestive tract help keep enzymes, acids, and wastes in the lumen from reaching the basolateral surfaces and digesting or otherwise damaging the underlying tissues and organs.

Desmosomes. Most epithelial cells are subject to mechanical stresses—stretching, bending, twisting, or compression—so they must have durable interconnections. At a **desmosome** (DEZ-mō-sōm; *desmos*, ligament + *soma*, body), CAMs and proteoglycans link the opposing plasma membranes. Desmosomes are very strong and can resist stretching and twisting.

A typical desmosome is formed by components from two cells. Within each cell, a complex known as a *dense area* is connected to the cytoskeleton. This connection to the cytoskeleton gives the desmosome—and the epithelium—its strength. For example, desmosomes are abundant between cells in the superficial layers of the skin. As a result, damaged skin cells are usually lost in sheets rather than as individual cells. (That is why skin peels rather than sheds as a powder after a sunburn.)

There are two types of desmosomes:

- *Spot desmosomes* are small discs connected to bands of intermediate filaments (**Figure 4-3d**). The intermediate filaments stabilize the shape of the cell.
- *Hemidesmosomes* resemble half of a spot desmosome. Rather than attaching one cell to another, a hemidesmosome attaches a cell to extracellular filaments in the basement membrane (**Figure 4-3e**). This attachment helps stabilize the position of the epithelial cell and anchors it to underlying tissues.

Attachment to the Basement Membrane

Not only do epithelial cells hold onto one another, but they also remain firmly connected to the rest of the body. In fact, epithelial cells must be attached to other cells, or they will die. The inner surface of each epithelium is attached to a two-part basement membrane composed of a basal lamina and a reticular lamina. The layer closer to the epithelium, the *basal lamina*, is an amorphous, ill-organized layer thought to function as a selective filter (**Figure 4-3e**). It is secreted by the adjacent layer of epithelial cells. The basal lamina restricts the movement of proteins and other large molecules from the underlying connective tissue into the epithelium.

Figure 4-3 Cell Junctions.

Which is the only type of cell junction shown here that allows the diffusion of ions and molecules between cells?

The deeper portion of the basement membrane, the *reticular lamina*, consists mostly of reticular fibers and ground substance. These connective tissue components are discussed later in the chapter. This layer gives the basement membrane its strength. Attachments between the fibers of the basal lamina and those of the reticular lamina hold the two layers together, and hemidesmosomes attach the epithelial cells to the composite basement membrane. The reticular lamina also acts as a filter that determines what substances can diffuse between the adjacent tissues and the epithelium.

Epithelial Maintenance and Repair

Epithelial cells lead hard lives. They are exposed to disruptive enzymes, toxic chemicals, pathogenic bacteria, physical distortion, and mechanical abrasion. Consider the lining of the small intestine, where epithelial cells are exposed to a variety of enzymes and abraded by partially digested food. In this extreme environment, an epithelial cell may last just a day or two before it is shed or destroyed. The only way the epithelium can maintain its structure over time is by the continual division of *stem cells*. Most epithelial stem cells are located near the basement membrane, in a relatively protected location.

✓ Checkpoint

- 4
3. Identify four essential functions of epithelial tissue.

4. List five important characteristics of epithelial tissue.

5. What is the probable function of an epithelium whose cells bear microvilli?

6. Identify the various types of epithelial cell junctions.

7. What is the functional significance of gap junctions?

See the blue Answers tab at the back of the book.

4-3 Cell shape and number of layers determine the classification of epithelia

Learning Outcome Describe the relationship between structure and function for each type of epithelium.

Recall that epithelial tissue includes epithelia and glands. The glands are either attached to or derived from epithelia.

Classification of Epithelia

There are many different specialized types of epithelia. These types are sorted into categories based on (1) the cell shape and (2) the number of cell layers between the basement membrane and the exposed surface of the epithelium. Using these two criteria, we can describe almost every epithelium in the body.

Epithelial cells have three basic shapes: *squamous*, *cuboidal*, and *columnar* (Table 4-1). To classify by shape, we look at the superficial cells in a section perpendicular to both the apical surface and the basement membrane. In sectional view, squamous cells appear thin and flat like scales, cuboidal cells look like little boxes, and columnar cells are tall and relatively slender rectangles.

Once you have determined whether the superficial cells are squamous, cuboidal, or columnar, then look at the number of cell layers. There are only two options: *simple* or *stratified*.

If only one layer of cells covers the basement membrane, that layer is a **simple epithelium**. Simple epithelia are necessarily thin. All the cells have the same polarity, so the distance from the nucleus to the basement membrane does not change from one cell to the next.

Because they are so thin, simple epithelia are fragile. A single layer of cells cannot provide much mechanical protection, so simple epithelia are located only in protected areas inside the body. They line internal compartments and passageways, such as the pleural, pericardial, and peritoneal cavities; the heart chambers; and blood vessels.

Simple epithelia are also characteristic of regions in which secretion or absorption occurs. Examples are the lining of the intestines and the gas-exchange surfaces of the lungs. In these places, thinness is an advantage. It reduces the time required for materials to cross the epithelial barrier.

Table 4-1 Classifying Epithelia

	Simple	Stratified
Squamous	 Simple squamous epithelium	 Stratified squamous epithelium
Cuboidal	 Simple cuboidal epithelium	 Stratified cuboidal epithelium
Columnar	 Simple columnar epithelium	 Stratified columnar epithelium

In a **stratified epithelium**, several layers of cells cover the basement membrane. Stratified epithelia are generally located in areas that are exposed to mechanical or chemical stresses. The surface of the skin and the lining of the mouth are examples.

Tips

To help you remember the meanings of the terms *squamous* and *stratified*, associate the word “squamous” with “scaly,” and the word “stratified” with “stratosphere,” an upper **layer** of Earth’s atmosphere.

Squamous Epithelia

The cells in a **squamous epithelium** (SKWĀ-mus; *squama*, scale) are thin, flat, and somewhat irregular in shape, like pieces of a jigsaw puzzle (Figure 4-4). From the surface, the cells resemble fried eggs laid side by side. In sectional view, the disc-shaped nucleus occupies the thickest portion of each cell (Table 4-1).

Figure 4-4 Squamous Epithelia.**a Simple Squamous Epithelium**

LOCATIONS: Mesothelia lining pleural, pericardial, and peritoneal cavities; endothelia lining heart and blood vessels; portions of kidney tubules (thin sections of nephron loops); inner lining of cornea; alveoli of lungs

FUNCTIONS: Reduces friction; controls vessel permeability; performs absorption and secretion

**Lining of peritoneal cavity****b Stratified Squamous Epithelium**

LOCATIONS: Surface of skin; lining of mouth, throat, esophagus, rectum, anus, and vagina

FUNCTIONS: Provides physical protection against abrasion, pathogens, and chemical attack

**Surface of tongue****LM × 310**

A **simple squamous epithelium** is the body's most delicate type of epithelium. This type of epithelium is in protected regions where absorption or diffusion takes place, or where a slick, slippery surface reduces friction. Examples are the respiratory exchange surfaces (*alveoli*) of the lungs, the lining of the thoracic and abdominopelvic body cavities of the trunk (**Figure 4-4a**), and the lining of the heart and blood vessels. Smooth linings are extremely important. For example, any irregularity in the lining of a blood vessel may result in the formation of a potentially dangerous blood clot.

Special names have been given to the simple squamous epithelia that line chambers and passageways that do not communicate with the outside world. The simple squamous epithelium that lines the body cavities enclosing the lungs, heart, and abdominal organs is called a **mesothelium** (mez-ō-THĒ-lē-um; *mesos*, middle). The pleura, pericardium, and peritoneum each contain a superficial layer of mesothelium. The simple squamous epithelium lining the inner surface of the heart and all blood vessels is called an **endothelium** (en-dō-THĒ-lē-um; *endo-*, inside).

A **stratified squamous epithelium** (**Figure 4-4b**) is generally located where mechanical stresses are severe. The cells

form a series of layers, like the layers in a sheet of plywood. The surface of the skin and the lining of the mouth, esophagus, and anus are areas where this type of epithelium protects against physical and chemical attacks.

On exposed body surfaces, where mechanical stress and dehydration are potential problems, superficial layers of epithelial cells are packed with filaments of the protein *keratin*. As a result, these layers are both tough and water resistant. Such an epithelium is said to be *keratinized*. A *nonkeratinized* stratified squamous epithelium resists abrasion but will dry out and deteriorate unless kept moist. Nonkeratinized stratified squamous epithelia are found in the oral cavity, pharynx, esophagus, anus, and vagina.

Cuboidal Epithelia

The cells of a **cuboidal epithelium** resemble hexagonal boxes from their apical surfaces. (In typical sectional views they appear square.) The spherical nuclei are near the center of each cell, and the distance between adjacent nuclei is about equal to the height of the epithelium.

A **simple cuboidal epithelium** provides limited protection and occurs where secretion or absorption takes place.

Such an epithelium makes up glands and lines portions of the kidney tubules (**Figure 4–5a**).

Stratified cuboidal epithelia are relatively rare. They are located along the ducts of sweat glands (**Figure 4–5b**) and in the larger ducts of the mammary glands.

4 Transitional Epithelia

A **transitional epithelium** is an unusual stratified epithelium because its cells can change between being squamous and cuboidal in shape (**Figure 4–5c**). Unlike most epithelia, it tolerates repeated cycles of stretching without damage. It is called transitional because the appearance of the epithelium changes as stretching occurs. A transitional epithelium is found in regions of the urinary system, such as the urinary bladder, where large changes in urine volume occur. In an empty urinary bladder, the superficial cells of the epithelium are typically plump and cuboidal. In a full urinary bladder, when the volume of urine has stretched the lining to its limits, the epithelium appears flattened, and more like a stratified squamous epithelium.

Columnar Epithelia

In a typical sectional view, **columnar epithelial cells** appear rectangular. In reality, the densely packed cells are hexagonal, but they are taller and thinner than cells in a cuboidal epithelium (**Figure 4–6**). The elongated nuclei are crowded into a narrow band close to the basement membrane. The height of the epithelium is several times the distance between adjacent nuclei.

A **simple columnar epithelium** is typically found where absorption or secretion takes place, such as in the small intestine (**Figure 4–6a**). In the stomach and large intestine, the secretions of simple columnar epithelia protect against chemical stresses.

Portions of the respiratory tract contain a **pseudostratified columnar epithelium**, a columnar epithelium that includes several types of cells with varying shapes and functions. The distances between the cell nuclei and the exposed surface vary, so the epithelium appears to be layered, or stratified (**Figure 4–6b**). It is not truly stratified, though, because every epithelial cell contacts the basement membrane. Pseudostratified columnar epithelial cells typically have cilia. Epithelia of this type line most of the nasal cavity, the trachea (windpipe), the bronchi (branches of the trachea leading to the lungs), and portions of the male reproductive tract.

Stratified columnar epithelia are relatively rare, providing protection along portions of the pharynx, epiglottis, anus, and urethra, as well as along a few large excretory ducts. The epithelium has either two layers or multiple layers (**Figure 4–6c**). In the latter case, only the superficial cells are columnar.

Glandular Epithelia

Many epithelia contain gland cells that are specialized for secretion; these are known as **glandular epithelia**. Collections of epithelial cells (or structures derived from epithelial cells) that produce secretions are called **glands**. They range from scattered cells to complex glandular organs. There are two main types of glands, classified by where they deliver their secretions. *Endocrine glands* release their secretions into the blood, whereas *exocrine glands* release their secretions directly onto an epithelial surface or into passageways called *ducts* that open onto an epithelial surface. Most glands in the body produce either exocrine or endocrine secretions. However, a few complex organs, including the digestive tract and the pancreas, produce both kinds of secretions.

Endocrine Glands

An **endocrine gland** produces *endocrine* (*endo-*, inside + *krino*, to separate) *secretions*, called **hormones**. These hormones enter the bloodstream for distribution throughout the body. Hormones regulate or coordinate the activities of various tissues, organs, and organ systems. Because their secretions are not released into ducts, endocrine glands are often called *ductless glands*.

Examples of endocrine glands include the thyroid gland, thymus, and pituitary gland. Endocrine glands, which are separate organs, are made up of endocrine cells. Endocrine cells may also be present outside of a gland as part of an epithelial surface, such as the lining of the digestive tract. We examine endocrine glands, cells, and hormones further in Chapter 18.

Exocrine Glands

Exocrine glands produce *exocrine* (*exo-*, outside) *secretions*, which are discharged onto an epithelial surface. Most exocrine secretions reach the surface through tubular **ducts**, which empty onto the skin surface or onto an epithelium lining an internal passageway that communicates with the exterior. Examples of exocrine secretions are enzymes entering the digestive tract, perspiration on the skin, tears in the eyes, and milk produced by mammary glands.

We classify exocrine glands from three perspectives: (1) the structure of the glands, (2) how such glands secrete their products, and (3) the nature of those products.

Gland Structure. The first method of classifying exocrine glands is by structure. In epithelia that have independent, scattered gland cells, the individual secretory cells are called **unicellular glands**. **Multicellular glands** include glandular epithelia and aggregations of gland cells that produce exocrine or endocrine secretions.

In “simple columnar epithelium,” which word describes cell shape and which word describes the number of cell layers?

Figure 4-7 A Structural Classification of Exocrine Glands.

Unicellular exocrine glands consist of single cells called **goblet cells** that are specialized for secretion. Like mucous cells, goblet cells secrete *mucin*, which mixes with water to form a sticky lubricant called **mucus**. Their location determines whether they are termed *goblet cells* or *mucous cells*. Goblet cells are scattered among the absorptive cells in the columnar epithelium of the small and large intestines. Mucous cells are scattered among other epithelial tissues.

The simplest **multicellular exocrine gland** is a *secretory sheet*, in which gland cells form an epithelium that releases secretions into an inner compartment. Mucin-secreting cells that line the stomach, for instance, protect that organ from its own acids and enzymes by continuously secreting mucin.

Most other multicellular exocrine glands are in pockets set back from the epithelial surface. Their secretions travel through one or more ducts to the surface. Examples include the salivary glands, which produce mucins and digestive enzymes.

Three characteristics are useful in describing the structure of multicellular exocrine glands (**Figure 4-7**):

- The Structure of the Duct.** A gland is *simple* if it has a single duct that does not divide on its way to the gland cells (**Figure 4-7a**). The gland is *compound* if the duct divides one or more times on its way to the gland cells (**Figure 4-7b**).
- The Shape of the Secretory Portion of the Gland.** Glands whose glandular cells form tubes are *tubular*; the tubes may be straight or coiled. Those that form blind pockets are *alveolar* (al-VĒ-ō-lar; *alveolus*, sac) or *acinar* (AS-i-nar; *acinus*, chamber). Glands whose secretory cells form both tubes and pockets are called *tubulo-alveolar* and *tubulo-acinar*.
- The Relationship between the Ducts and the Glandular Areas.** A gland is *branched* if several secretory areas (tubular or acinar) share a duct. ("Branched" refers to the glandular areas and not to the duct.)

+ Clinical Note Exfoliative Cytology

Exfoliative (eks-FŌ-lē-a-tiv; ex-, from + *folium*, leaf) *cytology* is the study of cells shed or removed from epithelial surfaces. Cells can be examined for changes that indicate cancer or for genetic screening of a fetus. Cells are collected from epithelia lining the respiratory, digestive, urinary, or reproductive tract; from the pleural, pericardial, or peritoneal body cavities; or from an epithelial surface. The harvesting of epithelial cells interrupts their intercellular junctions.

One such common sampling procedure is a *Pap test*, named after Dr. George Papanicolaou, who pioneered its use. The most familiar Pap test involves scraping cells from the tip of the *cervix*, the portion of the uterus that projects into the vagina, to screen for cancer.

Amniocentesis (am-nē-oh-sen-TĒ-sis) collects shed epithelial cells from a sample of *amniotic fluid*, which surrounds and protects a developing fetus. Examination of these cells can determine if the fetus has a chromosomal abnormality, such as occurs in *Down's syndrome*, also called *trisomy 21*.

Methods of Secretion. Exocrine glands are made up of exocrine cells, which use one of three different methods to secrete their products: (1) *merocrine secretion*, (2) *apocrine secretion*, or (3) *holocrine secretion*.

In **merocrine** (MER-ō-krin; *meros*, part) **secretion**, the product is released from an exocrine cell by secretory vesicles through exocytosis (Figure 4-8a). This is the most common method of exocrine secretion. For example, mucin is a merocrine secretion. The mucous secretions of the salivary glands coat food and reduce friction during swallowing. In the skin, merocrine sweat glands produce the watery perspiration that helps cool the body on a hot day.

Apocrine (AP-ō-krin; *apo-*, off) **secretion** from an exocrine cell involves the loss of cytoplasm as well as the secretory product (Figure 4-8b). The apical portion of the cytoplasm becomes packed with secretory vesicles and is then shed. Milk production in the mammary glands involves a combination of merocrine and apocrine secretions.

Merocrine and apocrine secretions leave a cell relatively intact and able to continue secreting. **Holocrine** (HOL-ō-krin; *holos*, entire) **secretion**, by contrast, destroys the gland cell. During holocrine secretion, a superficial cell in a stratified glandular epithelium becomes packed with secretory vesicles and then bursts, releasing the secretion, but killing the cell (Figure 4-8c). Further secretion depends on replacing destroyed gland cells by the division of underlying stem cells. Sebaceous glands, associated with hair follicles, produce an oily hair coating by means of holocrine secretion.

Types of Secretions. Finally, we also categorize exocrine glands by the types of secretions they produce:

- *Serous glands* secrete a watery solution that contains enzymes. The parotid salivary glands are serous glands.
- *Mucous glands* secrete mucins that hydrate to form mucus. The sublingual salivary glands and the submucosal glands of the small intestine are mucous glands.
- *Mixed exocrine glands* contain more than one type of gland cell. These glands may produce two different exocrine secretions, one serous and the other mucous. The submandibular salivary glands are mixed exocrine glands.

✓ Checkpoint

8. Identify the three cell shapes characteristic of epithelial cells.
9. When classifying epithelial tissue, one with a single layer of cells is called _____, whereas one with multiple layers of cells is called _____.
10. Viewed with a light microscope, a tissue appears as a simple squamous epithelium. Can this be a sample of the skin surface? Why or why not?
11. Why do the pharynx, esophagus, anus, and vagina have a similar stratified epithelial organization?
12. Name the two primary types of glandular epithelia.
13. The secretory cells of sebaceous glands fill with vesicles and then rupture, releasing their contents. This describes which method of secretion?
14. Which type of gland releases its secretions directly into the interstitial fluid?

See the blue Answers tab at the back of the book.

4-4 Connective tissue has varied roles in the body that reflect the physical properties of its three main types

Learning Outcome List the specific functions of connective tissue and describe the three main categories of connective tissue.

It is impossible to discuss epithelial tissue without mentioning an associated type of tissue: **connective tissue**, a diverse group of supporting tissues. Recall that the reticular lamina layer of the basement membrane of all epithelial tissues is made up of connective tissue components. In essence, connective tissue connects the epithelium to the rest of the body. Other types of connective tissue include bone, fat, and blood.

Connective tissues vary widely in appearance and function, but they all share three basic components: (1) specialized cells, (2) extracellular protein fibers, and (3) a fluid known as *ground substance*. Together, the extracellular fibers

Figure 4-8 Methods of Glandular Secretion.

Which method of secretion destroys the cell?

and ground substance make up the **matrix**, which surrounds the cells. While cells make up the bulk of epithelial tissue, the matrix typically accounts for most of the volume of connective tissues.

Connective tissues occur throughout the body, but they are never exposed to the outside environment. Many connective tissues are highly vascular (that is, they have many blood vessels) and contain sensory receptors that detect pain, pressure, temperature, and other stimuli.

The specific functions of connective tissues include the following:

- Establishing a structural framework for the body.
- Transporting fluids and dissolved materials.
- Protecting delicate organs.
- Supporting, surrounding, and interconnecting other types of tissue.
- Storing energy, especially in the form of triglycerides.
- Defending the body from invading microorganisms.

We classify connective tissues by their physical properties. The three general categories of connective tissue are *connective tissue proper*, *fluid connective tissues*, and *supporting connective tissues*.

- **Connective tissue proper** includes those connective tissues with many types of cells and extracellular fibers in a viscous (syrupey) ground substance. This broad category contains a variety of connective tissues that are grouped into *loose connective tissues* and *dense connective tissues*. These groupings are based on the number of cell types present, and on the relative properties and proportions of fibers and ground substance. Both *adipose tissue*, or fat (a loose connective tissue), and *tendons* (a dense connective tissue) are connective tissue proper, but they have very different structural and functional characteristics.
- **Fluid connective tissues** have distinctive populations of cells suspended in a watery matrix that contains dissolved proteins. The only two types are *blood* and *lymph*.
- **Supporting connective tissues** differ from connective tissue proper in having a less diverse cell population and a matrix containing much more densely packed fibers. Supporting connective tissues protect soft tissues and support the weight of part or all the body. The two types of supporting connective tissues are *cartilage* and *bone*. (The matrix of cartilage is a gel with characteristics that vary with the predominant type of fiber. The matrix of bone contains mineral deposits, primarily calcium salts, that provide rigidity.)

This concludes our general overview of connective tissue. The next three sections explore these three types in more detail.

Checkpoint

15. Identify several functions of connective tissues.
16. List the three categories of connective tissues.

See the blue Answers tab at the back of the book.

4-5 Connective tissue proper includes loose connective tissues that fill internal spaces and dense connective tissues that contribute to the internal framework of the body

Learning Outcome Compare the structures and functions of the various types of connective tissue proper and describe the layers of connective tissue called fascia.

In this section we describe the cells and extracellular materials of connective tissue proper and the structure and function of loose and dense connective tissues. We also describe embryonic connective tissues.

Structure of Connective Tissue Proper

Connective tissue proper contains a varied cell population. It also contains a matrix made up of extracellular fibers and a viscous ground substance (**Figure 4-9**). Let's look at each of these components.

Connective Tissue Proper Cell Populations

Some cells in connective tissue proper function in local maintenance, repair, and energy storage. These cells include *fibroblasts*, *fibrocytes*, *adipocytes*, and *mesenchymal cells*. All are permanent residents of the connective tissue. Other cells defend and repair damaged tissues. These cells are more motile and include *macrophages*, *mast cells*, *lymphocytes*, *plasma cells*, and *microphages*. They are not permanent residents, but they do migrate through healthy connective tissues and collect at sites of tissue injury. The number of cells and cell types in a tissue at any moment varies with local conditions.

The fixed and migratory cells of connective tissue proper include the following:

- **Fibroblasts** (FĪ-brō-blasts) are the only cells that are *always* present in connective tissue proper. They are also the most abundant fixed residents of connective tissue proper. Fibroblasts secrete hyaluronan (a polysaccharide derivative) and proteins. (Recall that hyaluronan is one of the ingredients that helps lock epithelial cells together.) In connective tissue proper, extracellular fluid, hyaluronan, and proteins interact to form the proteoglycans that make ground substance viscous. Each fibroblast also secretes protein subunits that assemble to form large extracellular fibers.

Figure 4-9 The Cells and Fibers of Connective Tissue Proper. A diagrammatic view of the cell types and fibers of connective tissue proper. (Macrophages, not shown, are common only in damaged or abnormal tissues.)

engulf damaged cells or pathogens that enter the tissue. (Their name literally means “big eater.”) Although not abundant, macrophages are important in mobilizing the body’s defenses. When stimulated, they release chemicals that activate the immune system and attract large numbers of additional macrophages and other cells involved in tissue defense.

Macrophages are either *fixed macrophages*, which spend long periods in a tissue, or *free macrophages*, which migrate rapidly through tissues. In effect, fixed macrophages provide a “frontline” defense that can be reinforced by the arrival of free macrophages and other specialized cells.

- **Fibrocytes** (FĪ-brō-sĭtz) are the second most abundant fixed cell in connective tissue proper. They differentiate from fibroblasts. Fibrocytes are spindle-shaped cells that maintain the connective tissue fibers of connective tissue proper.
- **Adipocytes** (AD-i-pō-sĭtz) are also known as fat cells. A typical adipocyte contains a single, enormous lipid droplet. The nucleus, other organelles, and cytoplasm are squeezed to one side, making a sectional view of the cell resemble a class ring. The number of adipocytes varies from one type of connective tissue to another, from one region of the body to another, and among individuals.
- **Mesenchymal cells** are stem cells that are present in many connective tissues. These cells respond to local injury or infection by dividing to produce daughter cells that differentiate into fibroblasts, macrophages, or other connective tissue cells.
- **Melanocytes** (me-LAN-ō-sĭtz) synthesize and store the brown pigment **melanin** (MEL-a-nin), which gives tissues a dark color. Melanocytes are common in the epithelium of the skin, where they play a major role in determining skin color. Melanocytes are also abundant in connective tissues of the eye and the dermis of the skin, although the number present differs by body region and among individuals.
- **Macrophages** (MAK-rō-fā-jez) are large phagocytic cells scattered throughout the matrix. These scavengers engulf damaged cells or pathogens that enter the tissue. (Their name literally means “big eater.”) Although not abundant, macrophages are important in mobilizing the body’s defenses. When stimulated, they release chemicals that activate the immune system and attract large numbers of additional macrophages and other cells involved in tissue defense.
- **Mast cells** circulate in the blood in an immature form before they migrate to other vascularized tissues (tissues with blood vessels) and undergo final maturation. The cytoplasm of a mast cell is filled with granules containing **histamine** (HIS-tuh-mēn) and **heparin** (HEP-uh-rin). Histamine, released after injury or infection, stimulates local inflammation. (The inflammatory effects of histamine are familiar if you’ve had a cold. People often take antihistamines to reduce cold symptoms.) *Basophils*, blood cells that enter damaged tissues and enhance the inflammation process, also contain granules of histamine and heparin. The level of heparin in the blood is normally low. It is an anticoagulant that enhances local blood flow during inflammation and reduces the development of blood clots in areas of slow-moving blood.
- **Lymphocytes** (LIM-fō-sĭtz) migrate throughout the body, traveling through connective tissues and other tissues. Their numbers increase markedly wherever tissue damage occurs. Some lymphocytes may develop into **plasma cells**, which produce *antibodies*—proteins involved in defending the body against disease.
- **Microphages** [*neutrophils* and *eosinophils* (ē-ō-SIN-ō-filz)] are phagocytic blood cells that normally move through connective tissues in small numbers. They are attracted to the site of an infection or injury by chemicals released by macrophages and mast cells.

Connective Tissue Fibers

Three types of fibers occur in connective tissue proper: *collagen*, *reticular*, and *elastic fibers* (Figure 4–9). Fibroblasts form all three by secreting protein subunits that interact in the matrix. Fibrocytes then maintain these fibers.

- **Collagen fibers** are the most common fibers in connective tissue proper. They are long, straight, and unbranched. Each collagen fiber consists of a bundle of fibrous protein subunits wound together like the strands of a rope. A collagen fiber is flexible like a rope, but it is stronger than steel when pulled from either end. Tendons, which connect skeletal muscles to bones, consist almost entirely of collagen fibers. *Ligaments* are similar to tendons, but they connect one bone to another bone. Tendons and ligaments can withstand tremendous forces. Uncontrolled muscle contractions or skeletal movements are more likely to break a bone than to snap a tendon or a ligament.
- **Reticular fibers** (*reticulum*, network) contain the same protein subunits as do collagen fibers, but they are arranged differently. Thinner than collagen fibers, reticular fibers form a branching, interwoven framework that is tough, yet flexible. Reticular fibers resist forces applied from many directions because they form a network rather than share a common alignment. This interwoven network, called a *stroma*, stabilizes the relative positions of the functional cells, or *parenchyma* (pa-RENG-ki-ma), of organs such as the liver. Reticular fibers also stabilize the positions of an organ's blood vessels, nerves, and other structures, despite changing positions and the pull of gravity.
- **Elastic fibers** contain the protein *elastin*. Elastic fibers are branched and wavy. After stretching, they return to their

original length. *Elastic ligaments*, which are dominated by elastic fibers, are rare but have important functions, such as interconnecting vertebrae.

Ground Substance

Ground substance fills the spaces between cells and surrounds connective tissue fibers (Figure 4–9). In connective tissue proper, ground substance is clear, colorless, and viscous (due to the presence of proteoglycans and glycoproteins). Ground substance is viscous enough that bacteria have trouble moving through it—imagine swimming in molasses. This viscosity slows the spread of pathogens and makes them easier for phagocytes to catch.

Loose Connective Tissues

Loose connective tissues are the “packing materials” of the body. They fill spaces between organs, cushion and stabilize specialized cells in many organs, and support epithelia. These tissues surround and support blood vessels and nerves, store lipids, and provide a route for the diffusion of materials. Loose connective tissues include *mucous connective tissue* in embryos and *areolar tissue*, *adipose tissue*, and *reticular tissue* in adults.

Embryonic Connective Tissues

Mesenchyme (MEZ-en-kīm), or *embryonic connective tissue*, is the first connective tissue to appear in a developing embryo. Mesenchyme contains an abundance of star-shaped stem cells (mesenchymal cells) separated by a matrix with very fine protein filaments (Figure 4–10a). Mesenchyme gives rise to all other connective tissues. **Mucous connective tissue** (Figure 4–10b), or *Wharton's jelly*, is a loose connective tissue found in many parts of the embryo, including the umbilical cord.

Figure 4–10 Embryonic Connective Tissues.

a This is the first connective tissue to appear in an embryo.

b This sample was taken from the umbilical cord of a fetus.

Adults have neither form of embryonic connective tissue. Instead, many adult connective tissues contain scattered mesenchymal stem cells that can assist in tissue repair after an injury.

Areolar Tissue

Areolar tissue (a-rē-uh-lur; *areola*, little space) is the least specialized connective tissue in adults. It may contain all the cells and fibers of any connective tissue proper in a very loosely organized array (**Figure 4-11a**). Areolar tissue has an open framework. A viscous ground substance provides most of its volume and absorbs shocks. Areolar tissue can distort without damage because its fibers are loosely organized. Elastic fibers make it resilient, so areolar tissue returns to its original shape after external pressure is relieved.

Areolar tissue forms a layer that separates the skin from deeper structures. In addition to providing padding, the elastic properties of this layer allow a considerable amount of independent movement. For this reason, pinching arm skin will not affect the underlying muscle. Conversely, contractions of the underlying muscle do not pull against the skin: As the muscle bulges, the areolar tissue stretches. The areolar tissue layer under the skin is a common injection site for drugs because it has an extensive blood supply.

The capillaries (thin-walled blood vessels) in areolar tissue deliver oxygen and nutrients and remove carbon dioxide and waste products. They also carry wandering cells to and from the tissue. Epithelia commonly cover areolar tissue, and fibrocytes maintain the reticular lamina of the basement membrane that separates the two kinds of tissue. The epithelial cells rely on the oxygen and nutrients that diffuse across the basement membrane from capillaries in the underlying connective tissue.

Adipose Tissue

The distinction between areolar tissue and fat, or **adipose tissue**, is a matter of degree. Adipocytes (fat cells) account for most of the volume of adipose tissue (**Figure 4-11b**), but only a fraction of the volume of areolar tissue. Adipose tissue provides padding, absorbs shocks, acts as an insulator to slow heat loss through the skin, and serves as packing or filler around structures. Adipose tissue is common under the skin of the sides (between the last rib and the hips), buttocks, and breasts. It fills the bony sockets behind the eyes and surrounds the kidneys. It is also common beneath the mesothelial lining of the pericardial and peritoneal cavities.

Most of the adipose tissue in the body is called **white fat**, because it has a pale, yellow-white color. In infants and young children, however, the adipose tissue between the shoulder blades, around the neck, and possibly elsewhere in the upper body is highly vascularized, and the individual adipocytes contain numerous mitochondria. Together, these characteristics give the tissue a deep, rich color, leading to the name

Clinical Note Marfan Syndrome

Marfan syndrome is an inherited condition caused by the production of an abnormally weak form of *fibrillin*, a glycoprotein that gives strength and elasticity to connective tissues. The effects of this defect are widespread because most organs contain connective tissues. The most visible sign of Marfan syndrome involves the skeleton. Most individuals with the condition are tall and have abnormally long limbs and fingers. The most serious consequences involve the cardiovascular system. About 90% of people with Marfan syndrome have structural abnormalities in their cardiovascular system. The most dangerous possibility is that the weakened elastic connective tissues in the walls of major arteries, such as the aorta, may burst, causing a sudden, fatal loss of blood.

brown fat. When these cells are stimulated by the nervous system, lipid breakdown speeds up. The cells do not capture the energy that is released. Instead, the surrounding tissues absorb it as heat. The heat warms the circulating blood, which distributes the heat throughout the body. In this way, an infant can double its metabolic heat generation very quickly. Until recently, it was thought that adults had little, if any, active brown fat tissue. However, recent evidence has indicated that it is most likely present in adults, and that its absence may be connected to obesity.

Adipocytes are not simply fat storage bins. Instead, they are metabolically active cells. Their lipids are constantly being broken down and replaced. When nutrients are scarce, adipocytes deflate like collapsing balloons as their lipids are broken down and the fatty acids are released to support metabolism.

What happens if nutrients become plentiful again? The lost weight can easily be regained in the same areas of the body because the cells are not killed but merely reduced in size. In adults, adipocytes cannot divide. The number of fat cells in peripheral tissues is established in the first few weeks of a newborn's life, perhaps in response to the amount of fats in the diet. However, that is not the end of the story, because loose connective tissues also contain mesenchymal cells. If circulating lipid levels are chronically elevated, the mesenchymal cells will divide, giving rise to cells that differentiate into fat cells. As a result, areas of areolar tissue can become adipose tissue in times of nutritional plenty, even in adults.

Liposuction is a cosmetic surgical procedure that removes excess or unwanted adipose tissue. However, liposuction provides only a temporary and potentially risky solution to the problem of excess weight. Once again, the reason is that adipose tissue can regenerate through the differentiation of mesenchymal cells.

LM $\times$ 230

Which type of loose connective tissue provides padding, cushions shock, reduces heat loss, and stores energy? Where are some places in the body this type of tissue is commonly found?

Reticular Tissue

As mentioned earlier, organs such as the liver, kidney, and spleen contain **reticular tissue**, in which reticular fibers form a complex three-dimensional stroma (**Figure 4-11c**). The stroma supports the functional cells of these organs. This fibrous framework is also found in the lymph nodes and bone marrow. Fixed macrophages, fibroblasts, and fibrocytes are associated with the reticular fibers, but these cells are seldom visible in microscopic sections, because specialized cells with other functions dominate the organs.

Dense Connective Tissues

Fibers create most of the volume of **dense connective tissues**. These tissues are often called **collagenous** (ko-LAJ-e-nus) **tissues** because collagen fibers are the dominant type of fiber in them. The body has two types of dense connective tissues: *dense regular connective tissue* and *dense irregular connective tissue*. *Elastic tissue* is a specialized type of dense regular connective tissue.

Dense Regular Connective Tissue

In **dense regular connective tissue**, the collagen fibers are parallel to each other, packed tightly, and aligned with the forces applied to the tissue. **Tendons** are cords of dense regular connective tissue that attach skeletal muscles to bones (**Figure 4-12a**). The collagen fibers run longitudinally along the tendon and transfer the pull of the contracting muscle to the bone. **Ligaments** resemble tendons but connect one bone to another or stabilize the positions of internal organs.

An **aponeurosis** (AP-ō-noo-RŌ-sis; plural, *aponeuroses*) is a tendinous sheet that attaches a broad, flat muscle to another muscle or to several bones of the skeleton. It can also stabilize the positions of tendons and ligaments. Aponeuroses are associated with large muscles of the skull, lower back, and abdomen, and with the tendons and ligaments of the palms of the hands and the soles of the feet. Large numbers of fibroblasts are scattered among the collagen fibers of tendons, ligaments, and aponeuroses.

Dense Irregular Connective Tissue

In contrast to dense regular connective tissue, the fibers in **dense irregular connective tissue** form an interwoven meshwork in no consistent pattern (**Figure 4-12b**). These tissues strengthen and support areas subjected to stresses from many directions. A layer of dense irregular connective tissue gives the deep layer of the skin, called the *dermis*, its strength. Cured leather (animal skin) is an excellent example of the interwoven nature of this tissue. Dense irregular connective tissue forms a thick fibrous layer called a *capsule*, which surrounds internal organs such as the liver, kidneys, and spleen and encloses the

cavities of joints. Except at joints, dense irregular connective tissue also forms a sheath around cartilages (the *perichondrium*) and bones (the *periosteum*).

Elastic Tissue

Dense regular and dense irregular connective tissues contain variable amounts of elastic fibers. When elastic fibers outnumber collagen fibers, the tissue has a springy, resilient nature that allows it to tolerate cycles of extension and recoil. Abundant elastic fibers are present in the connective tissue that supports transitional epithelia, in the walls of large blood vessels such as the aorta, between erectile tissue and the skin of the penis, and around the respiratory passageways.

Elastic tissue is a dense regular connective tissue made up mainly of elastic fibers. Elastic ligaments are almost completely dominated by elastic fibers. They help stabilize the positions of the vertebrae of the spinal column (**Figure 4-12c**).

Fascia: Layers of Connective Tissue Proper

As discussed earlier, connective tissue provides the internal structure of the body. Layers of connective tissue surround and support the organs within the trunk cavities and connect them to the rest of the body. These layers (1) provide strength and stability, (2) maintain the relative positions of internal organs, and (3) supply a route for the distribution of blood vessels, lymphatic vessels, and nerves.

Fascia (FASH-ē-uh; plural, *fasciae*, FASH-ē-ē) is a connective tissue wrapping that supports and surrounds organs. We can divide the fascia into three layers: the superficial fascia, the deep fascia, and the subserous fascia (**Figure 4-13**).

1. The **superficial fascia** refers to the *subcutaneous layer*. This layer of areolar and adipose tissue separates the skin from underlying tissues and organs. It also provides insulation and padding and lets the skin and underlying structures move independently.
2. The **deep fascia** consists of sheets of dense regular connective tissue. The organization of the fibers is like that of a sheet of plywood: In each layer making up the sheet, all fibers run in the same direction, but the orientation of the fibers changes from layer to layer. This arrangement helps the tissue resist forces coming from many directions. The tough capsules that surround most organs, including the kidneys and the organs enclosed by the thoracic and peritoneal cavities, are bound to this fascia layer. The perichondrium around cartilages, the periosteum around bones and the ligaments that interconnect them, and the connective tissues of muscle (including tendons) are also connected to the deeper fascia layer. Because the function of deep fascia differs by location, it is referred to more specifically as *muscular fascia*, *parietal fascia*, and *visceral fascia*.

Figure 4–12 Dense Connective Tissues.**a Dense Regular Connective Tissue**

Figure 4–13 The Fascia. The relationships among the connective tissue layers in the body.

The dense connective tissue components are interwoven. For example, fascia around a muscle blends into the tendon, whose fibers intermingle with those of the periosteum. This arrangement creates a strong, fibrous network and binds structural elements together.

- The **subserous fascia** is a layer of areolar tissue that lies between the deep fascia and the serous membranes that line true body cavities. Because this layer separates the serous membranes from the deep fascia, movements of muscles or muscular organs do not severely distort the delicate body cavity linings.

✓ Checkpoint

- Identify the cells found in connective tissue proper.
- Lack of vitamin C in the diet interferes with the ability of fibroblasts to produce collagen. What effect might this interference have on connective tissue?
- Many people with allergies take antihistamines to relieve their allergy symptoms. Which cells produce the substance that this medication blocks?
- Which type of connective tissue contains primarily triglycerides?
- Name the three layers of fascia and their types of connective tissue.

See the blue Answers tab at the back of the book.

4-6 Blood and lymph are fluid connective tissues that transport cells and dissolved materials

Learning Outcome Describe the fluid connective tissues blood and lymph and explain their relationship with interstitial fluid in maintaining homeostasis.

Blood and lymph are fluid connective tissues with distinctive collections of cells. The fluid matrix that surrounds the cells also includes many types of suspended proteins that, under normal conditions, do not form insoluble fibers.

In **blood**, the watery matrix is called **plasma**. Plasma contains blood cells and fragments of cells, collectively known as *formed elements*. There are three types of formed elements: red blood cells, white blood cells, and platelets (**Figure 4–14**).

Recall from Chapter 3 that an extracellular fluid called interstitial fluid surrounds the cells of the human body. In terms of decreasing volume, the three major subdivisions of extracellular fluid are *interstitial fluid*, *plasma*, and *lymph*.

Plasma is normally confined to the blood vessels (arteries, capillaries, and veins) of the cardiovascular system. Contractions of the heart keep it in motion. *Arteries* carry blood away from the heart and into the tissues of the body. In those tissues, blood pressure forces water and small solutes out of the bloodstream across the walls of *capillaries*, the smallest blood vessels. This process is the origin of the interstitial fluid

Figure 4-14 Formed Elements in the Blood.

Which formed element of the blood contains a nucleus?

that bathes the body's cells. The remaining blood flows from the capillaries into *veins* that return it to the heart.

Lymph forms as interstitial fluid enters *lymphatic vessels*. As fluid passes along the lymphatic vessels, cells of the immune system (lymphocytes) monitor its composition and respond to signs of injury or infection. The lymphatic vessels ultimately return the lymph to large veins near the heart. This recirculation of fluid—from the cardiovascular system, through the interstitial fluid, to the lymph, and then back to the cardiovascular system—is a continuous process that is essential to homeostasis. It helps eliminate local differences in the levels of nutrients, wastes, or toxins; maintains blood volume; and alerts the immune system to infections that may be under way in peripheral tissues.

Checkpoint

22. Which two types of connective tissue have a fluid matrix?
23. Describe the recirculation of fluid in the body.

See the blue Answers tab at the back of the book.

4-7 The supporting connective tissues cartilage and bone provide a strong framework

Learning Outcome Describe how cartilage and bone function as supporting connective tissues.

Cartilage and *bone* are called supporting connective tissues because they provide a strong framework that supports the rest of the body. The matrix of each tissue contains numerous fibers. In bone, it also contains deposits of insoluble calcium salts.

Cartilage

The matrix of **cartilage** is a firm gel that contains polysaccharide derivatives called **chondroitin sulfates** (kon-DROY-tin; *chondros*, cartilage). Chondroitin sulfates form complexes with proteins in the ground substance, producing proteoglycans. Cartilage cells, or **chondrocytes** (KON-drō-sītz), are the only cells in the cartilage matrix. They occupy small chambers known as **lacunae** (la-KOO-nē; *lacus*, lake). The physical properties of cartilage depend on the proteoglycans of the matrix, and on the type and abundance of extracellular fibers.

Unlike other connective tissues, cartilage is avascular, so all exchange of nutrients and waste products must take place by diffusion through the matrix. Because of this situation, cartilage heals poorly. Blood vessels do not grow into cartilage because chondrocytes produce a chemical that discourages their formation. This chemical inhibitor of new blood vessel formation is called *antiangiogenesis factor* (*anti-*, against + *angeion*, vessel + *genesis*, production). Other angiogenesis inhibitors have also been identified in the body or developed as drugs. Various inhibitors are now used in cancer treatments to discourage new blood vessel formation to tumors, thereby slowing tumor growth.

Cartilage is generally set apart from surrounding tissues by a fibrous **perichondrium** (per-i-KON-drē-um; *peri-*, around). The perichondrium contains two distinct layers: an outer, fibrous region of dense irregular connective tissue and an inner, cellular layer. The fibrous layer gives mechanical support and protection and attaches the cartilage to other structures. The cellular layer is important to the growth and maintenance

of the cartilage. Blood vessels in the perichondrium provide oxygen and nutrients to the underlying chondrocytes.

Types of Cartilage

The body contains three major types of cartilage: hyaline cartilage, elastic cartilage, and fibrocartilage.

- **Hyaline cartilage** (HĪ-uh-lin; *hyalos*, glass) is the most common type of cartilage. Except inside joint cavities, a dense perichondrium surrounds hyaline cartilages. Hyaline cartilage is tough but somewhat flexible because its matrix contains closely packed collagen fibers. Because these fibers are not in large bundles and do not stain darkly, they are not always apparent in light microscopy (**Figure 4-15a**). Examples in adults include the connections between the ribs and the sternum; the nasal cartilages and the supporting cartilages along the conducting passageways of the respiratory tract; and the *articular cartilages*, which cover opposing bone surfaces within many joints, such as the elbow and knee.
- **Elastic cartilage** (**Figure 4-15b**) is extremely resilient and flexible because it contains numerous elastic fibers. These cartilages usually have a yellowish color on gross dissection. Elastic cartilage forms the flap (the *auricle*) of the external ear; the *epiglottis*, which prevents food and liquids from entering the windpipe when swallowing; a passageway to the middle ear cavity (the *auditory canal*); and small cartilages (the *cuneiform cartilages*) in the larynx, or voice box.
- **Fibrocartilage** is extremely durable and tough because it has little ground substance and its matrix is dominated by densely interwoven collagen fibers (**Figure 4-15c**). Pads of fibrocartilage (*intervertebral discs*) lie between the spinal vertebrae, around tendons and within or around joints, and between the pubic bones of the pelvis. In these positions, fibrocartilage resists compression, absorbs shocks, prevents damaging bone-to-bone contact, and limits movement.

Cartilage Growth

Cartilage grows by two mechanisms: *interstitial growth* and *appositional growth*. **Interstitial growth** enlarges the cartilage from within (**Figure 4-16a**). Chondrocytes in the cartilage matrix divide, and the daughter cells produce additional matrix. Interstitial growth is most important during development. It begins early in embryonic development and continues through adolescence.

Appositional growth gradually increases the size of the cartilage by adding to its outer surface (**Figure 4-16b**). In this process, cells of the inner layer of the perichondrium divide repeatedly and become *chondroblasts* (immature chondrocytes). These cells begin producing cartilage matrix. As they become surrounded by and embedded in new matrix, they differentiate into mature chondrocytes, becoming part of the cartilage and so enlarging it.

Both interstitial and appositional growth take place during development, but interstitial growth contributes more to the mass of adult cartilage. Neither interstitial nor appositional growth takes place in the cartilages of normal adults. However, appositional growth may occur in unusual circumstances, such as after cartilage has been damaged or excessively stimulated by *growth hormone* from the pituitary gland. Minor damage to cartilage can be repaired by appositional growth at the damaged surface. After more severe damage, a dense fibrous patch will replace the injured portion of the cartilage.

Several complex joints, including the knee, contain both hyaline cartilage and fibrocartilage. The hyaline cartilage covers bony surfaces, and fibrocartilage pads in the joint prevent contact between bones during movement. Because injuries to these pads do not heal, such injuries can interfere with normal movements. After repeated or severe damage, joint mobility is severely reduced. Surgery generally produces only a temporary or incomplete repair.

Bone

Here we focus only on major differences between cartilage and bone. We examine the detailed histology of **bone**, or **osseous** (OS-ē-us; *os*, bone) **tissue**, in Chapter 6. The volume of ground substance in bone is very small. About two-thirds of the matrix of bone is **calcified**, consisting of a mixture of calcium salts—primarily calcium phosphate, with lesser amounts of calcium carbonate. The rest of the matrix is dominated by collagen fibers. This combination gives bone truly remarkable properties. By themselves, calcium salts are hard but rather brittle, whereas collagen fibers are strong but relatively flexible. In bone, the presence of the minerals surrounding the collagen fibers produces a strong, somewhat flexible combination that is highly resistant to shattering. In its overall properties, bone can compete with the best steel-reinforced concrete. In essence, the collagen fibers in bone act like the steel reinforcing rods, and the mineralized matrix acts like the concrete.

Figure 4-17 shows the general organization of bone. Lacunae in the matrix contain **osteocytes** (OS-tē-ō-sītz), or bone cells. The lacunae are typically organized around blood vessels in tubes called *central canals* that branch through the bony matrix. Diffusion cannot take place through the hard matrix, but osteocytes communicate with the blood vessels and with one another by means of slender cytoplasmic extensions. These extensions run through long, slender passageways in the matrix called **canaliculi** (kan-a-LIK-ū-lē; little canals). These passageways form a branching network for the exchange of materials between blood vessels, interstitial fluid, and osteocytes.

Except in joint cavities, where a layer of hyaline cartilage covers bone, the surfaces are sheathed by a **periosteum** (per-ē-OS-tē-um), a covering composed of fibrous (outer) and cellular (inner) layers. The periosteum helps to attach a bone to surrounding tissues and to associated tendons and ligaments. The cellular layer takes part in bone growth and helps with repairs after an injury.

Figure 4–15 Types of Cartilage.**a Hyaline Cartilage**

LOCATIONS: Between tips of ribs and bones of sternum; covering bone surfaces at synovial joints; supporting larynx (voice box), trachea, and bronchi; forming part of nasal septum

FUNCTIONS: Provides stiff but somewhat flexible support; reduces friction between bony surfaces

Figure 4–16 The Growth of Cartilage.

What is the only type of cell found in cartilage matrix?

Figure 4–17 Bone. The osteocytes in bone are generally organized in groups around a central canal that contains blood vessels.

Table 4–2 A Comparison of Cartilage and Bone

Characteristic	Cartilage	Bone
STRUCTURAL FEATURES		
Cells	Chondrocytes in lacunae	Osteocytes in lacunae
Ground substance	Chondroitin sulfate (in proteoglycans) and water	A small volume of liquid surrounding insoluble crystals of calcium salts (calcium phosphate and calcium carbonate)
Fibers	Collagen, elastic, and reticular fibers (proportions vary)	Collagen fibers predominate
Vascularity	None	Extensive
Covering	Perichondrium (two layers)	Periosteum (two layers)
Strength	Limited: bends easily, but hard to break	Strong: resists distortion until breaking point
METABOLIC FEATURES		
Oxygen demands	Low	High
Nutrient delivery	By diffusion through matrix	By diffusion through cytoplasm and interstitial fluid in canaliculi
Growth	Interstitial and appositional	Appositional only
Repair capabilities	Limited	Extensive

Unlike cartilage, bone undergoes extensive remodeling throughout life. Complete repairs can be made even after severe damage. Bones also respond to the stresses placed on them. They grow thicker and stronger with exercise and become thin and brittle with inactivity.

Table 4–2 summarizes the similarities and differences between cartilage and bone.

✓ Checkpoint

- 24. Identify the two types of supporting connective tissue.
- 25. Why does bone heal faster than cartilage?
- 26. If a person has a herniated intervertebral disc, characterized by displacement of the pad of cartilage between the vertebrae, which type of cartilage has been damaged?

See the blue Answers tab at the back of the book.

4-8 Tissue membranes made from epithelia and connective tissue make up four types of physical barriers

Learning Outcome Explain how epithelial and connective tissues combine to form four types of tissue membranes and specify the functions of each.

There are many different types of anatomical membranes. You learned that plasma membranes enclose cells in Chapter 3, and you will find many other kinds of membranes in later chapters. Here we are concerned with **tissue membranes** that form physical barriers by lining or covering body surfaces. Each such membrane consists of an epithelium supported by connective tissue. Four types of tissue membranes are found in the body: (1) *mucous membranes*, (2) *serous membranes*, (3) the *cutaneous membrane*, and (4) *synovial membranes* (Figure 4–18).

Mucous Membranes

Mucous membranes, or **mucosae** (mū-KŌ-sē), line passageways and chambers that open to the exterior, including those in the digestive, respiratory, urinary, and reproductive tracts (Figure 4–18a). The epithelial surfaces of these passageways must be kept moist to reduce friction and, in many cases, to facilitate absorption or secretion. The epithelial surfaces are lubricated either by mucus produced by mucous cells, or by fluids, such as urine or semen. The areolar tissue component of a mucous membrane is called the **lamina propria** (PRŌ-prē-uh). We also look at the organization of specific mucous membranes in later chapters.

Many mucous membranes contain simple epithelia that perform absorptive or secretory functions, such as the simple columnar epithelium of the digestive tract. However, other types of epithelia may be involved. For example, a stratified squamous epithelium is part of the mucous membrane of the mouth, and the mucous membrane along most of the urinary tract contains a transitional epithelium.

Serous Membranes

Serous membranes line the sealed, internal cavities of the trunk—cavities that are not open to the exterior. These membranes consist of a mesothelium supported by areolar tissue (Figure 4–18b). Recall from Chapter 1, the three types of serous membranes are (1) the *peritoneum*, which lines the peritoneal cavity and covers the surfaces of the enclosed organs; (2) the *pleura*, which lines the pleural cavities and covers the lungs; and (3) the *pericardium*, which lines the pericardial cavity and covers the heart. Serous membranes are very thin, but they are firmly attached to the body wall and to the organs they cover. When looking at an organ such as the heart or stomach, the tissues of the organ are seen through a transparent serous membrane.

Figure 4–18 Types of Membranes.

What is the name of the epithelium that lines the peritoneal cavity?

The primary function of any serous membrane is to minimize friction between the surfaces that it covers. Each serous membrane can be divided into a *parietal portion*, which lines the inner surface of the cavity, and an opposing *visceral portion*, or **serosa**, which covers the outer surfaces of visceral organs. These organs often move or change shape as they carry out their various functions, and the parietal and visceral surfaces of a serous membrane are always in close contact. Friction between these surfaces is kept to a minimum because mesothelia are very thin and permeable, and tissue fluids continuously diffuse onto the exposed surfaces, keeping them moist and slippery.

The slippery fluid secreted by the mesothelium of a serous membrane is called *serous fluid*. However, after an injury or in certain disease states where there is an imbalance of hydrostatic and osmotic forces, the volume of serous fluid, now called *transudate*, may increase dramatically. This change may complicate existing medical problems or produce new ones.

The Cutaneous Membrane

The **cutaneous membrane** is the skin that covers the body's surface. It consists of a keratinized stratified squamous epithelium and a layer of areolar tissue reinforced by

underlying dense irregular connective tissue (**Figure 4–18c**). In contrast to serous and mucous membranes, the cutaneous membrane is thick, relatively waterproof, and usually dry. We take a closer look at the cutaneous membrane in Chapter 5.

4

Synovial Membranes

Adjacent bones often interact at joints, or *articulations*. There the two articulating bones are very close together or in contact. Joints that permit significant amounts of movement are complex structures. A fibrous capsule surrounds such a joint, and the ends of the articulating bones lie within a *joint cavity* filled with **synovial** (si-NŌ-vē-ul) **fluid**. The synovial fluid is produced by a **synovial membrane**, which lines the joint cavity (**Figure 4–18d**).

A synovial membrane consists of two layers: areolar tissue and an atypical or unusual epithelium. The extensive area of areolar tissue contains a matrix of interwoven collagen fibers, proteoglycans, and glycoproteins. An incomplete layer, or sheet, of macrophages and specialized fibroblasts overlies and separates the areolar tissue from the joint cavity. These cells regulate the composition of the synovial fluid. This incomplete layer of cells is often called an epithelium, but it differs from true epithelia in four respects: (1) It develops within a connective tissue; (2) no basement membrane is present; (3) gaps of up to 1 mm may separate adjacent cells; and (4) fluid and solutes are continuously exchanged between the synovial fluid and capillaries in the underlying connective tissue.

Even though a smooth layer of articular (hyaline) cartilage covers the ends of the bones, the surfaces must be lubricated to keep friction from damaging the opposing surfaces. Synovial fluid provides the much-needed lubrication. This fluid is similar in composition to the ground substance in loose connective tissues. Synovial fluid circulates from the areolar tissue into the joint cavity and percolates through the articular cartilages, supplying oxygen and nutrients to the chondrocytes. Joint movement is important in stimulating the formation and circulation of synovial fluid: If a **synovial joint** is immobilized for long periods, the articular cartilages and the synovial membrane undergo degenerative changes.

Checkpoint

27. Identify the four types of tissue membranes found in the body.
28. Which cavities in the body are lined by serous membranes?
29. Which type of tissue membrane typically lines body passageways (such as the urinary tract) that open to the exterior?

See the blue Answers tab at the back of the book.

4-9 The three types of muscle tissue are skeletal, cardiac, and smooth

Learning Outcome Describe the three types of muscle tissue and the special structural features of each type.

Several vital functions involve movement of one kind or another—materials move along the digestive tract, blood flows within the vessels of the cardiovascular system, and the body itself moves from place to place. **Muscle tissue**, which is specialized for contraction, produces movement. Muscle cells have organelles and properties distinct from those of other cells.

There are three types of muscle tissue: (1) *skeletal muscle* forms the large muscles that produce gross body movements; (2) *cardiac muscle*, found in the heart, is responsible for circulating the blood; and (3) *smooth muscle* is found in the walls of visceral organs and a variety of other locations, where it contracts and provides support. The contraction mechanism is similar in all three types of muscle tissue, but the muscle cells differ in internal organization. We examine only general characteristics in this chapter and then discuss each type of muscle more fully in Chapter 10.

Skeletal Muscle Tissue

Skeletal muscle tissue contains very long muscle cells—up to 0.3 m (1 ft) or more in length. The individual muscle cells are usually called **muscle fibers** because they are relatively long and cylindrical (slender). Each muscle fiber has several hundred nuclei just inside the plasma membrane (**Figure 4–19a**). For this reason, the fibers are described as *multinucleate*.

Skeletal muscle fibers are incapable of dividing. New muscle fibers are produced instead through the divisions of **myo-satellite cells** (*muscle satellite cells*), stem cells that persist in adult skeletal muscle tissue. As a result, skeletal muscle tissue can at least partially repair itself after an injury.

As noted in Chapter 3, the cytoskeleton contains actin and myosin filaments. Actin and myosin interactions produce contractions. In skeletal muscle fibers, however, these filaments are organized into repeating patterns that give the cells a *striated*, or banded, appearance. The *striations*, or bands, are visible in light micrographs. Skeletal muscle fibers do not usually contract unless stimulated by nerves, and the nervous system provides voluntary control over their activities. Thus, skeletal muscle is called **striated voluntary muscle**.

Tips

Associate the sound of the word striated with the sound of the word **striped**.

A *skeletal muscle* is an organ of the muscular system. Although muscle tissue predominates, a muscle contains all four types of body tissue. Within a skeletal muscle, adjacent skeletal muscle fibers are tied together by collagen and elastic

Figure 4–19 Types of Muscle Tissue.**a** Skeletal Muscle Tissue

Cells are long, cylindrical, striated, and multinucleate.

LOCATIONS: Combined with connective tissues and neural tissue in skeletal muscles

FUNCTIONS: Moves or stabilizes the position of the skeleton; guards entrances and exits to the digestive, respiratory, and urinary tracts; generates heat; protects internal organs

**Skeletal muscle****b** Cardiac Muscle Tissue

Cells are short, branched, and striated, usually with a single nucleus; cells are interconnected by intercalated discs.

LOCATION: Heart

FUNCTIONS: Circulates blood; maintains blood pressure

**Cardiac muscle****c** Smooth Muscle Tissue

Cells are short, spindle shaped, and nonstriated, with a single, central nucleus.

LOCATIONS: Found in the walls of blood vessels and in digestive, respiratory, urinary, and reproductive organs

FUNCTIONS: Moves food, urine, and reproductive tract secretions; controls diameter of respiratory passageways; regulates diameter of blood vessels

**Smooth muscle**

Which muscle tissue consists of multinucleate cells?

fibers that blend into the attached tendon or aponeurosis. The tendon or aponeurosis conducts the force of contraction, often to a bone of the skeleton. When the muscles contract, they pull on the attached bone, producing movement.

Cardiac Muscle Tissue

- 4 **Cardiac muscle tissue** is found in the heart. A typical cardiac muscle cell is thinner and shorter than a skeletal muscle cell (**Figure 4–19b**). A typical cardiac muscle cell has one centrally positioned nucleus, but some cardiac muscle cells have as many as five. Prominent striations resemble those of skeletal muscle because the actin and myosin filaments are arranged the same way in the cells of both tissue types.

Cardiac muscle tissue consists of a branching network of interconnected cardiac muscle cells. The cells are connected at specialized regions known as **intercalated discs**. At intercalated discs the membranes are locked together by desmosomes, proteoglycans, and gap junctions. Ion movement through gap junctions helps synchronize the contractions of the cardiac muscle cells, and the desmosomes and proteoglycans lock the cells together during a contraction.

Cardiac muscle tissue has a very limited ability to repair itself. Some cardiac muscle cells do divide after an injury to the heart, but the repairs are incomplete. Some heart function is usually lost.

Cardiac muscle cells do not rely on nerve activity to start a contraction. Instead, specialized cardiac muscle cells called *pacemaker cells* set a regular rate of contraction. The nervous system can alter the rate of pacemaker cell activity, but it does not provide voluntary control over individual cardiac muscle cells. For this reason, cardiac muscle is called **striated involuntary muscle**.

Smooth Muscle Tissue

Smooth muscle tissue is found in the walls of blood vessels, around hollow organs such as the urinary bladder, and in layers around the digestive, respiratory, and reproductive tracts. A smooth muscle cell is short and spindle shaped, with tapering ends and a single, central nucleus (**Figure 4–19c**). These cells can divide, so smooth muscle tissue can regenerate after an injury.

The actin and myosin filaments in smooth muscle cells are organized differently from those of skeletal and cardiac muscles. One result is that smooth muscle tissue has no striations.

Smooth muscle cells may contract on their own, with gap junctions between adjacent cells coordinating the contractions of individual cells. The contraction of some smooth muscle tissue can be controlled by the nervous system, but contractile activity is not under voluntary control. [Imagine the effort needed to exert conscious control over the smooth muscles along the 8 m (26 ft) of digestive tract, not to mention the

miles of blood vessels!] Smooth muscle is known as **nonstriated involuntary muscle** because of its appearance and the fact that the nervous system usually does not voluntarily control smooth muscle contractions.

Checkpoint

30. Identify the three types of muscle tissue in the body.
31. Which type of muscle tissue has small, tapering cells with single nuclei and no obvious striations?
32. If skeletal muscle cells in adults are incapable of dividing, how is skeletal muscle repaired?

See the blue Answers tab at the back of the book.

4-10 Nervous tissue responds to stimuli and propagates electrical impulses throughout the body

Learning Outcome Discuss the basic structure and role of nervous tissue.

Nervous tissue is specialized for the propagation (movement) of electrical impulses from one region of the body to another. Ninety-eight percent of the nervous tissue in the body is in the brain and spinal cord, which are the control centers of the nervous system.

Nervous tissue contains two basic types of cells: (1) **neurons** (NŪ-ronz; *neuro*, nerve) and (2) several kinds of supporting cells, collectively called **neuroglia** (nū-ROG-lē-uh), or *glial cells* (*glia*, glue). Our conscious and unconscious thought processes reflect the communication among neurons in the brain. Such communication involves the propagation of electrical impulses, in the form of reversible changes in the membrane potential. The frequency of the electrical impulses relay information. Neuroglia support and repair nervous tissue and supply nutrients to neurons.

Neurons are the longest cells in the body. Many are as long as a meter (39 in.)! Most neurons cannot divide under normal circumstances, so they have a very limited ability to repair themselves after injury. A typical neuron has a large **cell body** with a nucleus and a prominent nucleolus (**Figure 4–20**). Extending from the cell body are many branching processes (projections or outgrowths) termed **dendrites** (DEN-drĭtz; *dendron*, a tree), and one **axon**. The dendrites receive information, typically from other neurons. The axon conducts that information to other cells. Because axons tend to be very long and slender, they are also called **nerve fibers**. In Chapter 12, we examine the properties of nervous tissue more closely.

Tips

To remember the direction of information flow in a neuron, associate the “t” in **dendrite** with “to” and the “a” in **axon** with “away.”

Figure 4–20 Nervous Tissue.

Checkpoint

33. A tissue contains irregularly shaped cells with many fibrous projections, some several centimeters long. These are probably which type of cell?

See the blue Answers tab at the back of the book.

4-11 The response to tissue injury involves inflammation and regeneration

Learning Outcome Describe how injuries affect the tissues of the body.

Now let's consider what happens after an injury, focusing on the interaction among different tissues. Our example includes connective tissue (blood), epithelium (the endothelia of blood vessels), muscle tissue (smooth in the vessel walls), and nervous tissue (sensory nerve endings). **Inflammation**, or the **inflammatory response**, is a process that isolates the injured area while damaged cells,

tissue components, and any dangerous microorganisms, which could cause *infection*, are cleaned up. **Regeneration** is the repair process that restores normal function after inflammation has subsided. In later chapters, especially Chapters 5 and 22, we consider inflammation and regeneration in more detail.

Inflammation

Stimuli that can produce inflammation include impact, abrasion, distortion, chemical irritation, infection by pathogenic organisms (such as bacteria or viruses), and extreme temperatures (hot or cold). Each of these stimuli kills cells, damages connective tissue fibers, or injures the tissue in some way. Such changes alter the chemical composition of the interstitial fluid: Damaged cells release prostaglandins, proteins, and potassium ions, and the injury itself may have introduced foreign proteins or pathogens into the body. Damaged connective tissue activates mast cells, which release chemicals that stimulate the inflammatory response.

Media resource available for this topic: Practice Anatomy Lab: Histology: Nervous Tissue

Tissue conditions soon become even more abnormal. **Necrosis** (ne-KRŌ-sis) is the tissue destruction that takes place after cells have been damaged or killed. It begins several hours after the original injury. Lysosomal enzymes cause the damage. Through widespread autolysis, lysosomes release enzymes that first destroy the injured cells and then attack surrounding tissues. The result may be **pus**, which is a collection of debris, fluid, dead and dying cells, and necrotic tissue components. An **abscess** is an accumulation of pus in an enclosed tissue space.

Regeneration

Each organ has a different ability to regenerate after injury. This ability is directly linked to the pattern of tissue organization in the injured organ. Epithelia, connective tissues (except cartilage), and smooth muscle tissue usually regenerate well, but skeletal and cardiac muscle tissues and nervous tissue regenerate relatively poorly, if at all. The skin, which is dominated by epithelia and connective tissues, regenerates rapidly and completely after injury. (We discuss the process in Chapter 5.) In contrast, damage to the heart is much more serious. The connective tissues of the heart can be repaired, but most damaged cardiac muscle cells are replaced only by fibrous tissue. The permanent replacement of normal tissue by fibrous tissue is called *fibrosis* (fī-BRŌ-sis). Fibrosis in muscle and other tissues may occur in response to injury, disease, or aging. **Spotlight Figure 4-21** shows the tissue response to injury and the process of tissue regeneration.

✓ Checkpoint

34. Identify the two phases in the response to tissue injury.
35. List the four common signs of inflammation.

4-12 With advancing age, tissue regeneration decreases and cancer rates increase

Learning Outcome Describe how aging affects the tissues of the body.

Aging has two important effects on tissues: The body's ability to repair damage to tissues decreases, and cancer is more likely to occur.

Aging and Tissue Structure

Tissues change with age, and the speed and effectiveness of tissue regeneration decrease. Repair and maintenance activities throughout the body slow down, and the rate of energy

consumption in general decreases. All these changes reflect various hormonal alterations that take place with age, often coupled with reduced physical activity and a more sedentary lifestyle. These factors combine to alter the structure and chemical composition of many tissues.

Epithelia get thinner and connective tissues more fragile. Individuals bruise more easily and bones become brittle. Joint pain and broken bones become more common as we age. Because cardiac muscle cells and neurons are not normally replaced, cumulative damage can eventually cause major health problems, such as cardiovascular disease or deterioration in mental functioning.

In later chapters, we consider the effects of aging on specific organs and systems. For example, the chondrocytes of older individuals produce a slightly different form of proteoglycan than do the chondrocytes of younger people. This difference probably accounts for the thinner and less resilient cartilage of older people.

In some cases, the tissue degeneration can be temporarily slowed or even reversed. Age-related reduction in bone strength, a condition called *osteoporosis*, typically results from a combination of inactivity, a low dietary calcium level, and a reduction in circulating sex hormones. A program of exercise that includes weight-bearing activity, calcium supplements, and, for some, medication, can generally maintain healthy bone structure for many years.

Aging and Cancer Incidence

Cancer rates increase with age, and about 25% of all people in the United States develop cancer at some point in their lives. An estimated 70–80% of cancer cases result from chemical exposure, environmental factors, or some combination of the two, and 40% of those cancers are caused by cigarette smoke. The development and growth of cancer was covered in Chapter 3.

This concludes the introductory portion of the book. In combination, the four basic tissue types described here form all the organs and body systems we discuss in upcoming chapters.

✓ Checkpoint

36. Identify some age-related factors that affect tissue repair and structure.
37. What would account for the observed increase in cancer rates with age?

See the blue Answers tab at the back of the book.

Tissues are not isolated, and they combine to form organs with diverse functions. Therefore, any injury affects several types of tissue simultaneously. To preserve homeostasis, the tissues must respond in a coordinated way. The restoration of homeostasis involves two related processes: inflammation and regeneration.

Mast Cell Activation

When an injury damages connective tissue, mast cells release a variety of chemicals. This process, called **mast cell activation**, stimulates inflammation.

Mast cell

Histamine
Heparin
Prostaglandins

stimulates

Exposure to Pathogens and Toxins

Injured tissue contains an abnormal concentration of pathogens, toxins, wastes, and the chemicals from injured cells.

INFLAMMATION

Inflammation produces several familiar indications of injury. These indications are the so-called *cardinal signs of inflammation*: redness, heat (warmth), swelling, pain, and sometimes loss of function. Inflammation may also result from the presence of pathogens, such as harmful bacteria, within the tissues. The presence of these pathogens constitutes an **infection**.

When a tissue is injured, a general defense mechanism is activated.

Increased Blood Flow

In response to the released chemicals, blood vessels dilate, increasing blood flow through the damaged tissue.

Increased Vessel Permeability

Vessel dilation is accompanied by an increase in the permeability of the capillary walls. Plasma now diffuses into the injured tissue, so the area becomes swollen.

Pain

The abnormal conditions within the tissue and the chemicals released by mast cells stimulate nerve endings that produce the sensation of pain.

Increased Local Temperature

The increased blood flow and permeability cause the tissue to become warm and red.

Increased Oxygen and Nutrients

Vessel dilation, increased blood flow, and increased vessel permeability result in enhanced delivery of oxygen and nutrients.

Increased Phagocytosis

Phagocytes in the tissue are activated, and they begin engulfing tissue debris and pathogens.

Removal of Toxins and Wastes

Enhanced circulation carries away toxins and wastes, distributing them to the kidneys for excretion, or to the liver for inactivation.

Regeneration

Regeneration is the repair that occurs after the damaged tissue has been stabilized and the inflammation has subsided. Fibroblasts move into the area, laying down a collagenous framework known as **scar tissue**. Over time, scar tissue is usually “remodeled” and gradually assumes a more normal appearance.

Inflammation Subsides

Over a period of hours to days, the cleanup process generally succeeds in eliminating the inflammatory stimuli.

Inhibits mast cell activation

Normal tissue conditions restored

4 Chapter Review

Study Outline

An Introduction to the Tissue Level of Organization

1. Tissues are structures with discrete structural and functional properties that combine to form organs.

4-1 The four tissue types are epithelial, connective, muscle, and nervous

2. **Tissues** are collections of specialized cells and cell products that perform a relatively limited number of functions. The four *tissue types* are *epithelial tissue*, *connective tissue*, *muscle tissue*, and *nervous tissue*. (Figure 4-1)
3. **Histology** is the study of tissues.

4-2 Epithelial tissue covers body surfaces, lines internal surfaces, and serves other essential functions

4. **Epithelial tissue** includes epithelia and glands. An **epithelium** is an **avascular** layer of cells that forms a barrier that provides protection and regulates permeability. **Glands** are secretory structures derived from epithelia. Epithelial cells may show **polarity**, the presence of structural and functional differences between their exposed (apical) and attached (basal) surfaces.
5. A **basement membrane** attaches epithelia to underlying connective tissues.
6. Epithelia provide physical protection, control permeability, provide sensation, and produce specialized secretions. Gland cells are epithelial cells that produce secretions. In **glandular epithelia**, most cells produce secretions.
7. Epithelial cells are specialized to perform secretory or transport functions and to maintain the physical integrity of the epithelium. (Figure 4-2)
8. Many epithelial cells have microvilli.
9. The coordinated beating of motile cilia on a **ciliated epithelium** moves materials across the epithelial surface.
10. Cells can attach to other cells or to extracellular protein fibers by means of **cell adhesion molecules (CAMs)** or at specialized attachment sites called **cell junctions**. The three major types of cell junctions are **tight junctions**, **gap junctions**, and **desmosomes**. (Figure 4-3)
11. The base of each epithelium is connected to a two-part basement membrane consisting of a *basal lamina* and a *reticular lamina*. Divisions by stem cells continually replace the short-lived epithelial cells.

4-3 Cell shape and number of layers determine the classification of epithelia

12. Epithelia are classified based on the number of cell layers and the shape of the cells at the apical surface.
13. A **simple epithelium** has a single layer of cells covering the basement membrane; a **stratified epithelium** has several layers. The cells in a **squamous epithelium** are thin and flat. Cells in a **cuboidal epithelium** resemble hexagonal boxes; those in a **columnar epithelium** are taller and thinner. (Table 4-1; Figures 4-4 to 4-6)

- Practice Anatomy Lab
- Interactive Physiology
- A&P Flix
- PhysioEx

14. Epithelial cells (or structures derived from epithelial cells) that produce secretions are called **glands**. **Exocrine glands** discharge secretions onto the body surface or into **ducts**, which communicate with the exterior. **Hormones**, the secretions of **endocrine glands**, are released by gland cells into the surrounding bloodstream.
15. In epithelia that contain scattered gland cells, individual secretory cells are called **unicellular glands**. **Multicellular glands** are organs that contain glandular epithelia that produce exocrine or endocrine secretions.
16. Exocrine glands can be classified based on structure as **unicellular exocrine glands** or as **multicellular exocrine glands**. Multicellular exocrine glands can be further classified according to structure. **Goblet cells** and **mucous cells** secrete mucin. (Figure 4-7)
17. A glandular epithelial cell may release its secretions by merocrine, apocrine, or holocrine secretory methods. In **merocrine secretion**, the most common method, the product is released through exocytosis. **Apocrine secretion** involves the loss of both the secretory product and cytoplasm. Unlike the other two methods, **holocrine secretion** destroys the gland cell, which becomes packed with secretions and then bursts. (Figure 4-8)

4-4 Connective tissue has varied roles in the body that reflect the physical properties of its three main types

18. **Connective tissues** are internal tissues with many important functions: establishing a structural framework; transporting fluids and dissolved materials; protecting delicate organs; supporting, surrounding, and interconnecting tissues; storing energy reserves; and defending the body from microorganisms.
19. All connective tissues contain specialized cells and a **matrix**, composed of extracellular protein fibers and a **ground substance**.
20. **Connective tissue proper** is connective tissue that contains varied cell populations and fiber types surrounded by a syrupy ground substance.
21. **Fluid connective tissues** have distinctive populations of cells suspended in a watery matrix that contains dissolved proteins. The two types of fluid connective tissues are *blood* and *lymph*.
22. **Supporting connective tissues** have a less diverse cell population than connective tissue proper and a dense matrix with extracellular fibers. The two types of supporting connective tissues are *cartilage* and *bone*.

4-5 Connective tissue proper includes loose connective tissues that fill internal spaces and dense connective tissues that contribute to the internal framework of the body

23. Connective tissue proper contains fibers, a viscous ground substance, and a varied population of cells, including **fibroblasts**, **fibrocytes**, **macrophages**, **adipocytes**, **mesenchymal cells**, **melanocytes**, **mast cells**, **lymphocytes**, and **microphages**. (Figure 4-9)
24. The three types of fibers in connective tissue are **collagen fibers**, **reticular fibers**, and **elastic fibers**.
25. The first connective tissue to appear in an embryo is **mesenchyme**, or **embryonic connective tissue**. (Figure 4-10)
26. Connective tissue proper is classified as either **loose connective tissue** or **dense connective tissue**. Loose connective tissues are mesenchyme and **mucous connective tissues** in the embryo; **areolar tissue**; **adipose tissue**, including **white fat** and **brown fat**; and **reticular tissue**. Most of the volume in dense connective tissue consists of extracellular fibers. The two types of dense connective tissue are **dense regular connective tissue** and **dense irregular connective tissue**. **Elastic tissue** is a dense regular connective tissue. (Figures 4-11, 4-12)
27. A network of connective tissue proper ties internal organs and systems together. This network consists of the **superficial fascia** (*subcutaneous layer*, separating the skin from underlying tissues and organs), the **deep fascia** (dense regular connective tissue), and the **subserous fascia** (the layer between the deep fascia and the serous membranes that line true body cavities). (Figure 4-13)

4-6 Blood and lymph are fluid connective tissues that transport cells and dissolved materials

28. **Blood** and **lymph** are connective tissues that contain distinctive collections of cells in a fluid matrix.
29. Blood contains *formed elements*: **red blood cells** (*erythrocytes*), **white blood cells** (*leukocytes*), and **platelets**. The watery matrix of blood is called **plasma**. (Figure 4-14)
30. **Arteries** carry blood away from the heart and toward **capillaries**, where water and small solutes move into the interstitial fluid of surrounding tissues. **Veins** return blood to the heart.
31. **Lymph** forms as interstitial fluid enters the lymphatic vessels, which return lymph to the cardiovascular system.

4-7 The supporting connective tissues cartilage and bone provide a strong framework

32. Cartilage and bone are called supporting connective tissues because they support the rest of the body.
33. **Chondrocytes**, or cartilage cells, rely on diffusion through the avascular matrix to obtain nutrients.
34. The matrix of cartilage is a firm gel that contains **chondroitin sulfates** (used to form proteoglycans) and chondrocytes. Chondrocytes occupy chambers called **lacunae**. A fibrous **perichondrium** separates cartilage from surrounding tissues. The three types of cartilage are **hyaline cartilage**, **elastic cartilage**, and **fibrocartilage**. (Figure 4-15)
35. **Cartilage** grows by two mechanisms: **interstitial growth** and **appositional growth**. (Figure 4-16)
36. **Bone**, or **osseous tissue**, consists of **osteocytes**, little ground substance, and a dense, mineralized matrix. Osteocytes are situated in lacunae. The matrix consists of calcium salts and collagen fibers, giving it unique properties. (Figure 4-17; Table 4-2)

37. Osteocytes depend on diffusion within **canaliculi** for nutrient intake.
38. Each bone is surrounded by a **periosteum** with fibrous and cellular layers.

4-8 Tissue membranes made from epithelia and connective tissue make up four types of physical barriers

39. Membranes form a barrier or interface. Epithelia and connective tissues combine to form membranes that cover and protect other structures and tissues. (Figure 4-18)
40. **Mucous membranes** line cavities that communicate with the exterior. They contain areolar tissue called the **lamina propria**.
41. **Serous membranes** line the body's sealed internal cavities of the trunk. They secrete a fluid called serous fluid.
42. The **cutaneous membrane**, or skin, covers the body surface.
43. **Synovial membranes** form an incomplete lining within the cavities of synovial joints and secrete **synovial fluid**.

4-9 The three types of muscle tissue are skeletal, cardiac, and smooth

44. **Muscle tissue** is specialized for contraction. (Figure 4-19)
45. The cells of **skeletal muscle tissue** are **multinucleate**. Skeletal muscle, or **striated voluntary muscle**, produces new fibers by the division of **myosatellite cells**, a type of stem cell.
46. The **cardiac muscle cells** of **cardiac muscle tissue** occur only in the heart. Cardiac muscle, or **striated involuntary muscle**, relies on *pacemaker cells* to stimulate regular contraction.
47. **Smooth muscle tissue**, or **nonstriated involuntary muscle**, is not striated. Smooth muscle cells can divide and therefore regenerate after injury.

4-10 Nervous tissue responds to stimuli and propagates electrical impulses throughout the body

48. **Nervous tissue** propagates electrical impulses, which convey information from one area of the body to another.
49. Cells in nervous tissue are either neurons or neuroglia. **Neurons** transmit information as electrical impulses. Several kinds of **neuroglia** (*glial cells*) exist, and their basic functions include supporting nervous tissue and helping supply nutrients to neurons. (Figure 4-20)
50. A typical neuron has a **cell body**, several **dendrites**, and an **axon** or **nerve fiber**. The axon carries information to other cells.

4-11 The response to tissue injury involves inflammation and regeneration

51. Any injury affects several types of tissue simultaneously, and the tissues respond in a coordinated manner. Two processes restore homeostasis: inflammation and regeneration.
52. **Inflammation**, or the **inflammatory response**, isolates the injured area while damaged cells, tissue components, and any dangerous microorganisms (which could cause **infection**) are cleaned up. **Regeneration** is the repair process that restores normal function. (Spotlight Figure 4-21)

4-12 With advancing age, tissue regeneration decreases and cancer rates increase

53. Tissues change with age. Repair and maintenance become less efficient, and the structure and chemical composition of many tissues are altered.
54. The incidence of cancer increases with age, with about three-quarters of all cases caused by exposure to chemicals or by other environmental factors, such as cigarette smoke.

Review Questions

See the blue Answers tab at the back of the book.

LEVEL 1 Reviewing Facts and Terms

1. Identify the six types of epithelial tissue shown in the drawing below.

(a) _____ (b) _____
(c) _____ (d) _____
(e) _____ (f) _____

2. While studying the human body, your students correctly classify the pancreas as a(n) (a) aggregate of cells, (b) tissue, (c) organ system, (d) organ, (e) organism.
3. Tissue that is specialized for filling internal spaces is (a) muscle tissue, (b) nervous tissue, (c) connective tissue, (d) epithelial tissue.
4. One of the important features of epithelial tissue is its (a) high vascularity, (b) poor regenerative capacity, (c) strong polarity, (d) lack of cell junctions.
5. Inferior to which type of cell junction would you find a continuous adhesion belt? (a) gap junction, (b) tight junction, (c) spot desmosome, (d) hemidesmosome.
6. The epithelia of the _____ permit repeated cycles of stretching without damage. (a) urinary bladder, (b) ducts of sweat glands, (c) bronchi, (d) large intestine.
7. The cavities of joints permitting significant amounts of movement are lined by the membrane. (a) cutaneous, (b) mucous, (c) synovial, (d) serous.
8. Cells that are permanent residents of connective tissue proper are (a) fibroblasts, (b) macrophages, (c) mast cells, (d) plasma cells.
9. Which type of epithelium allows for repeated stretching without getting damaged? (a) stratified squamous, (b) cuboidal, (c) transitional, (d) glandular.
10. There are several types of loose and dense connective tissues. Which type of adult connective tissue is the least specialized? (a) areolar, (b) elastic, (c) white fat, (d) brown fat, (e) reticular.
11. Except in joint cavities, the surfaces of bones are sheathed by (a) fibrocartilage, (b) hyaline cartilage, (c) perichondrium, (d) periosteum.
12. The primary function of serous membranes in the body is to (a) minimize friction between opposing surfaces, (b) line cavities that communicate with the exterior, (c) perform absorptive and secretory functions, (d) cover the surface of the body.
13. Fibrocartilage is found in (a) a part of the nasal septum, (b) the auditory canal, (c) intervertebral discs, (d) between the pubic bones of the pelvis, (e) both c and d.
14. Tissue changes with age can result from (a) hormonal changes, (b) increased need for sleep, (c) improper nutrition, (d) all of these, (e) a and c only.

15. Long, cylindrical, striated, and cells are characteristic of (a) smooth muscle tissue, (b) skeletal muscle tissue, (c) nervous tissue, (d) connective tissue.
16. The repair process necessary to restore normal function after inflammation subsides in damaged tissues is (a) isolation, (b) regeneration, (c) reconstruction, (d) all of these.
17. What are the four essential functions of epithelial tissue?
18. Differentiate between endocrine and exocrine glands.
19. By what three methods do exocrine glandular epithelial cells release their secretions?
20. List three basic components of connective tissues.
21. What are the four kinds of membranes composed of epithelial and connective tissue that cover and protect other structures and tissues in the body?
22. What two cell populations make up nervous tissue? What is the function of each?

LEVEL 2 Reviewing Concepts

23. Compare the ways in which salivary glands and mammary glands secrete their products.
24. A significant structural feature in the digestive system is the presence of tight junctions near the exposed surfaces of cells lining the digestive tract. Why are these junctions so important?
25. Cardiac muscle and skeletal muscle tissue are both striated. Give two unique distinctions between cardiac muscle tissue and skeletal muscle tissue.
26. Why does the skin peel in sheets rather than shed off as powder after a sunburn?
27. Mesenchyme, the first connective tissue to appear in a developing embryo, is composed of (a) neurons, (b) star-shaped stem cells, (c) white and brown fat cells, (d) collagen fibers, (e) reticular and elastic fibers.
28. Appositional growth of cartilage (a) includes division of chondrocytes in the cartilage matrix and production of additional matrix by the daughter cells, (b) is a normal mechanism to enlarge the cartilage from within, (c) includes repeated division of the cells of the inner layer of the perichondrium till they become chondroblasts, (d) results in extensive remodeling of cartilage throughout life, (e) is a common event in the cartilage of normal adults.
29. Describe the similarities and differences between the superficial and the deep fascia.

LEVEL 3 Critical Thinking and Clinical Applications

30. Doctor Rios has a large and diverse medical practice. Not all her patients have the same chance of being affected by osteoporosis. Which group of patients has more chance of being affected and why?
31. During a lab practical, a student examines a tissue that is composed of densely packed protein fibers that run parallel to each other and form a cord. There are no striations, but small nuclei are visible. The student identifies the tissue as skeletal muscle. Why is the student's choice wrong, and what tissue is the student probably observing?
32. Susan is told that cervical cancer can be detected early by regular screening tests and, hence, can be either prevented or treated more effectively. She is advised to get a Pap test done. What does this test involve?

CLINICAL CASE Wrap-Up Rubber Joints

Anne Marie was diagnosed with a variant of *Ehlers-Danlos* (Ä-lerz DAHN-los) *syndrome*—a rare inherited connective tissue disorder. Specifically, the collagen fibers in the matrix of connective tissue are defective. Because connective tissue and collagen occur throughout the body, many tissues are involved, particularly the joints and skin.

Anne Marie's loose joints and dislocations result from deficient dense connective tissue. Because of abnormal collagen fibers, both her ligaments (which connect bone to bone) and her tendons (which connect muscle to bone) are abnormally loose and heal poorly when overstretched. When she twists her knee and feels as if her kneecap is dislocating, it is, indeed, sliding out of its groove. The ligaments that protect her ankles have been repeatedly sprained.

Thin, translucent skin that is soft, velvety, and stretchy is also typical of Ehlers-Danlos syndrome. Scars appear wide, fragile, and abnormal. Bruises and skin tears occur easily.

1. Connective tissues are made up of specialized cells, a matrix of extracellular protein fibers, and a viscous fluid known as ground substance. What component of connective tissue proper is defective in Ehlers-Danlos syndrome?
2. Does this genetic syndrome affect just Anne Marie's joints and skin, or would other tissues also be affected?

See the blue Answers tab at the back of the book.

Related Clinical Terms

autopsy: An examination of a dead body to discover the cause of death or the extent of disease.

biopsy: An examination of tissue removed from a living body to discover the presence, cause, or extent of disease.

cachexia: Weakness and wasting of the body due to severe chronic illness.

carcinoma: A cancer arising in the epithelial tissue of the skin or of the lining of the internal organs.

immunotherapy: The prevention or treatment of disease with substances that stimulate the immune response.

lesion: A region in an organ or tissue that is damaged from injury or disease; a wound, ulcer, abscess, or tumor, for example.

metaplasia: A reversible structural change that alters the tissue.

pathologist: A physician who specializes in the study of disease processes in tissues and body fluids.

remission: Abatement, ending, or lessening in severity of the signs and symptoms of a disease.

sarcoma: A malignant tumor of connective or other nonepithelial tissue.

tissue engineering: The process of growing tissue either inside or outside of a body to be transplanted into a patient or used for testing.

tissue rejection: Occurs when a transplant recipient's immune system attacks a transplanted organ or tissue.

tissue transplantation: Moving tissues (or organs) from one body and placing them into another body via medical procedures for the purpose of replacing the recipient's damaged or failing tissue (or organ).

tumor grading: A system used to classify a tumor based on how abnormal the cancer cells look under a microscope and how quickly the tumor is likely to grow and spread.

tumor staging: Defining at what point a patient is in the development of a malignant disease when the diagnosis is made.

xenotransplant: The process of grafting or transplanting organs or tissues between members of different species.

5

The Integumentary System

Learning Outcomes

These Learning Outcomes correspond by number to this chapter's sections and indicate what you should be able to do after completing the chapter.

- 5-1 ■ Describe the main structural features of the epidermis and explain the functional significance of each.
- 5-2 ■ Describe the structures and functions of the dermis.
- 5-3 ■ Describe the structures and functions of the subcutaneous layer.
- 5-4 ■ Explain what accounts for individual differences in skin color and discuss the response of melanocytes to sunlight exposure.
- 5-5 ■ Describe the interaction between sunlight and vitamin D₃ production.
- 5-6 ■ Describe the mechanisms that produce hair and explain the structural basis for hair texture and color.
- 5-7 ■ Discuss the various kinds of glands in the skin and list the secretions of those glands.
- 5-8 ■ Describe the anatomical structures of nails and explain how they are formed.
- 5-9 ■ Explain how the skin responds to injury and repairs itself.
- 5-10 ■ Summarize the effects of aging on the skin.

CLINICAL CASE

He Has Fish Skin!

I shook his hand and immediately I knew something was different about him. When Grandpa Will clasped my hand between both of his, I felt like my hand was sandwiched between two sheets of thick, shaggy sandpaper. There was none of the moistness or warmth of a usual handshake.

Grandpa Will's grandsons adored him, and the feeling was mutual! They lured him into chasing them around the backyard. Because it was a hot summer day, play lasted all of 15 minutes and then Grandpa

Will brought the gang back to the air-conditioned comfort of the house. He sank back into the recliner. He was flushed and breathing hard, but his shirt stayed dry and crisp—there wasn't a bead of sweat visible on him. The boys climbed onto his lap, laughing, as he encircled them with those coarse hands. "Oh, Grandpa, you feel like a fish!" **What is happening with Grandpa Will's integumentary system? To find out, turn to the Clinical Case Wrap-Up at the end of the chapter.**

An Introduction to the Integumentary System

People are probably more familiar with the skin than with any other organ system. No other organ system is as accessible and large as the **integumentary system**. Often referred to simply as the **integument** (in-TEG-ū-ment), this system makes up about 16% of total body weight. Its relatively large surface area, about $1.5\text{--}2\text{m}^2$ (16.1–21.5 sq. ft.), is continually abraded, attacked by microorganisms, irradiated by sunlight, and exposed to environmental chemicals. The integumentary system is the body's first line of defense against the outside world.

The integumentary system has two major parts: the **cutaneous membrane** (skin) and the **accessory structures** (Figure 5-1).

1. The cutaneous membrane has two components: the *epidermis* (*epi-*, above), or superficial epithelium, and the *dermis*, an underlying area of connective tissues.
2. The accessory structures include *hair* and *hair follicles*, *exocrine glands*, and *nails*. They are embedded in the dermis and project up to or above the surface of the epidermis.

The integument does not function alone. An extensive network of blood vessels branches through the dermis. Nerve fiber endings and *sensory receptors* monitor touch, pressure, temperature, and pain, providing valuable information to the central nervous system about the state of the body.

Deep to the dermis is a layer of loose connective tissue called the *subcutaneous layer* (*hypodermis*). The subcutaneous layer separates the integument from the deep fascia around other organs, such as muscles and bones. Although the subcutaneous layer is often considered separate from the integument, we consider it in this chapter because its connective tissue fibers are interwoven with those of the dermis.

The general functions of the integumentary system are summarized in Figure 5-2. These functions include:

- *Protection* of underlying tissues and organs against impact, abrasion, fluid loss, and chemical attack.
- *Excretion* of salts, water, and organic wastes by glands.
- *Maintenance of normal body temperature* through either insulation or evaporative cooling, as needed.
- *Production of melanin*, which protects underlying tissue from ultraviolet (UV) radiation.
- *Production of keratin*, which protects against abrasion and repels water.
- *Synthesis of vitamin D₃*, a steroid that is converted to *calcitriol*, a hormone important to normal calcium ion metabolism.
- *Storage of lipids* in adipocytes in the dermis and in adipose tissue in the subcutaneous layer.
- *Detection* of touch, pressure, pain, vibration, and temperature stimuli, and the relaying of that information to the nervous system. (We discuss these *general senses*, which provide information about the external environment, in Chapter 15.)
- *Coordination of the immune response* to pathogens and cancers in the skin.

5-1 The epidermis is a protective covering composed of layers with various functions

Learning Outcome Describe the main structural features of the epidermis and explain the functional significance of each.

The epidermis is a stratified squamous epithelium. Recall from Chapter 4 that such an epithelium provides physical protection for the dermis, prevents water loss, and helps keep microorganisms outside the body.

Figure 5–1 The Components of the Integumentary System.

What types of glands are found in the skin?

Like all epithelia, the epidermis is avascular. Because there are no local blood vessels, epidermal cells rely on the diffusion of nutrients and oxygen from capillaries within the dermis. As a result, the epidermal cells with the highest metabolic demands are found close to the basement membrane, where the diffusion distance is short. The superficial cells, far removed from the source of nutrients, are dead. **Spotlight Figure 5–3a** shows and describes the basic organization of the epidermis.

Cells of the Epidermis: Keratinocytes

Keratinocytes (ke-RAT-i-nō-sītz), the body's most abundant epithelial cells, dominate the epidermis. These cells form several layers and contain large amounts of the protein **keratin** (KER-a-tin; *keros*, horn). Keratin is a tough, fibrous protein that is also the basic structural component of hair and nails in humans.

Layers of the Epidermis

The two types of skin, thin and thick, differ in their number of layers of keratinocytes. **Thin skin**, which contains four layers of keratinocytes, covers most of the body surface. **Thick skin**,

which has five layers, is found on the palms of the hands and the soles of the feet. Note that the terms *thin* and *thick* refer to the relative thickness of the epidermis, not to the entire cutaneous membrane. **Spotlight Figure 5–3b** shows the five layers of keratinocytes in a section of the epidermis in an area of thick skin.

The boundaries between the layers are often difficult to see in a standard light micrograph. The various layers have Latin names beginning with the word *stratum* (plural, *strata*), which means "layer." The second part of the name refers to the function or appearance of the layer. The strata, in order from the basement membrane toward the free surface, are the *stratum basale*, the *stratum spinosum*, the *stratum granulosum*, the *stratum lucidum*, and the *stratum corneum*.

Stratum Basale

The deepest layer of the epidermis is the **stratum basale** (STRA-tum buh-SAL-āy, "basal layer") or *stratum germinativum* (jer-mi-na-TĒ-vum). Hemidesmosomes attach the cells of this layer to the basement membrane that separates the epidermis from the areolar tissue of the dermis. The stratum basale and the underlying dermis interlock, increasing

Figure 5-2 The Cutaneous Membrane and Accessory Structures of the Integumentary System.

5

the strength of the bond between the epidermis and dermis. The stratum basale forms **epidermal ridges**, which extend into the dermis and are adjacent to dermal projections called **dermal papillae** (pa-PIL-ē; singular, *papilla*; a nipple-shaped mound) that extend into the epidermis (see **Spotlight Figure 5-3a**). These ridges and papillae are important because the strength of the attachment is proportional to the surface area of the basement membrane. In other words, the more numerous and deeper the folds, the larger the area of attachment becomes.

Basal cells, or *germinative cells*, dominate the stratum basale. Basal cells are stem cells that divide to replace the more superficial keratinocytes that are shed at the epithelial surface.

Skin surfaces that lack hair also contain specialized epithelial sensory cells known as *tactile (Merkel) cells* scattered among the cells of the stratum basale. Each tactile cell together with a sensory nerve ending is called a **tactile disc**. The tactile cells are sensitive to touch and, when compressed, release chemicals that stimulate their associated sensory nerve endings. (The skin contains many other kinds of sensory receptors, as we will see in later sections.)

Variations in skin tone result from the synthesis of pigment by cells called *melanocytes*. These pigment cells are distributed throughout the stratum basale, with cell processes extending into more superficial layers.

Stratum Spinosum

Each time a stem cell divides, one of the daughter cells is pushed superficial to the stratum basale into the **stratum spinosum**. This stratum consists of 8 to 10 layers of keratinocytes bound together by desmosomes. The name *stratum spinosum*, which means “spiny layer,” refers to the fact that the cells look like miniature pincushions in standard histological sections. They look that way because the keratinocytes were processed with chemicals that shrank the cytoplasm but left the cytoskeletal elements and desmosomes intact. Some of the cells entering this layer from the stratum basale continue to divide, further increasing the thickness of the epithelium.

The stratum spinosum also contains cells that participate in the immune response. These cells are called *dendritic cells* (*dendron*, tree) because of their branching projections. They are also known as *Langerhans cells*. They stimulate defense against

a BASIC ORGANIZATION OF THE EPIDERMIS

The epidermis consists of stratified squamous epithelium. It is separated from the dermis by a basement membrane.

The stratum basale and the underlying dermis interlock, strengthening the bond between the two.

The epidermis forms epidermal ridges, which extend into the dermis and are adjacent to dermal papillae that project into the epidermis.

Thin skin contains four layers of keratinocytes, and is about as thick as the wall of a plastic sandwich bag (about 0.08 mm).

b LAYERS OF THE EPIDERMIS

The layers of the epidermis are best shown in a sectional view of thick skin. **Thick skin** contains a fifth layer, the *stratum lucidum*. Because thick skin also has a much thicker superficial layer (the *stratum corneum*), it is about as thick as a standard paper towel (about 0.5 mm).

c EPIDERMAL RIDGES OF THICK SKIN

Fingerprints reveal the pattern of epidermal ridges. The scanning electron micrograph to the right shows the ridges on a fingertip.

(1) microorganisms that manage to penetrate the superficial layers of the epidermis and (2) superficial skin cancers. We discuss dendritic cells and other cells of the immune response in Chapter 22.

Stratum Granulosum

Superficial to the stratum spinosum is the **stratum granulosum**, or “granular layer.” It consists of three to five layers of keratinocytes derived from the stratum spinosum. By the time cells are pushed into this layer, most have stopped dividing and have started making large amounts of keratin. As keratin fibers accumulate, the cells grow thinner and flatter, and their plasma membranes thicken and become less permeable. The keratinocytes also make a protein called **keratohyalin** (ker-a-tō-HĪ-a-lin), which forms dense cytoplasmic granules that promote dehydration of the cell as well as aggregation and cross-linking of the keratin fibers. The nuclei and other organelles then disintegrate, and the cells die. Further dehydration creates a tightly interlocked layer of cells that consists of keratin fibers surrounded by keratohyalin.

Stratum Lucidum

In the thick skin of the palms and soles, a glassy **stratum lucidum** (“clear layer”) covers the stratum granulosum. The cells in the stratum lucidum are flattened, densely packed, largely without organelles, and filled with keratin.

Stratum Corneum

At the exposed surface of both thick skin and thin skin is the **stratum corneum** (KOR-nē-um; *corneus*, horny). It normally contains 15 to 30 layers of keratinized cells. **Keratinization**, or *cornification*, is the formation of protective, superficial layers of cells filled with keratin. This process takes place on all exposed skin surfaces except the anterior surfaces of the eyes. The dead cells in each layer of the stratum corneum remain tightly interconnected by desmosomes. The connections are so secure that keratinized cells are generally shed in large groups or sheets rather than individually (think about peeling skin after a sunburn). It’s also interesting to note that every minute, we shed about 30,000 to 40,000 skin cells. That adds up to about 9 pounds of skin cells every year!

It takes 7 to 10 days for a cell to move from the stratum basale to the stratum corneum. The dead cells generally remain in the exposed stratum corneum for an additional 2 weeks before they are shed or washed away. This arrangement places the deeper portions of the epithelium and underlying tissues beneath a protective barrier of dead, durable, and expendable cells. Normally, the surface of the stratum corneum is relatively dry, which prevents growth of many microorganisms. Lipid secretions from sebaceous glands coat the surface, helping to prevent water loss or gain.

The contours of the skin surface follow the ridge patterns of the dermal papillae in the stratum basale, which vary from small conical pegs in thin skin to the complex whorls seen on the thick skin of the palms and soles. Ridges on the palms and soles increase the surface area of the skin and increase friction, ensuring a secure grip. The ridge patterns on the tips of the fingers are the basis of fingerprints (**Spotlight Figure 5–3c**). These ridge shapes are determined partially by the interaction of genes and partially by the intrauterine environment. That is, during fetal development our genes determine general characteristics, but the contact with amniotic fluid, another fetus (in the case of twins), or the uterine wall affects the ultimate pattern of a fetus’s fingerprints. So, while the fingerprint patterns of identical twins are similar, they are not identical. However, the pattern of epidermal ridges is unique and does not change throughout life.

The stratum corneum is water resistant, but not waterproof. Water from interstitial fluids slowly diffuses to the surface and evaporates into the surrounding air. A person loses about 500 mL (about 1 pint) of water in this way each day. The process is called **insensible perspiration**, because the water loss cannot be seen or felt (sensed). In contrast, a person is usually very aware of the **sensible perspiration** produced by active sweat glands.

Damage to the epidermis can increase the rate of insensible perspiration. If the damage breaks connections between superficial and deeper layers of the epidermis, fluid accumulates in pockets, or *blisters*, within the epidermis. (Blisters also form between the epidermis and dermis if the basement membrane is damaged.) If damage to the stratum corneum makes it less effective as a water barrier, the rate of insensible perspiration skyrockets, and a potentially dangerous fluid loss occurs. This loss is a serious consequence of severe burns and a complication in the condition known as *xerosis* (excessively dry skin).

Why do wrinkles form in the skin on the fingers and toes after a long soak in the bath? Previously, this effect was commonly explained as being due to the osmotic movement of water across the epithelium. That is, the fingertips absorb water and swell, making the skin wrinkle. However, such a process failed to explain why wrinkling did not occur if there was nerve damage in the fingers. It turns out that fingertips do not swell in water but actually shrink when they wrinkle, an effect caused by the constriction of underlying blood vessels. The effect is due to the autonomic nervous system, which functions mostly outside our awareness and controls blood vessel diameter. Is there any benefit to having wrinkled fingertips? Recent studies have shown that the wrinkles improve the ability to grip wet or submerged objects, much like the treads of a tire improve traction on a wet road.

Epidermal Growth Factor

Epidermal growth factor (EGF) is one of the peptide growth factors introduced in Chapter 3. EGF is produced by the salivary glands and glands of the duodenum (initial segment of

the small intestine). It was named for its effects on the epidermis, but we now know that EGF has widespread effects on epithelia throughout the body. Here are some roles of EGF:

- Promoting the divisions of basal cells in the stratum basale and stratum spinosum.
- Accelerating the production of keratin (keratinization) in differentiating keratinocytes.
- Stimulating epidermal development and epidermal repair after injury.
- Stimulating secretory product synthesis and secretion by epithelial glands.

5

In the procedure known as *tissue culture*, cells are grown under laboratory conditions for experimental or therapeutic use. Epidermal growth factor has such a pronounced effect that it can be used in tissue culture to stimulate the growth and division of epidermal cells (or other epithelial cells). Using human epidermal growth factor (hEGF) produced through recombinant DNA technology, it is now possible to grow sheets of epidermal cells for use in treating severe or extensive burns. The burned areas can be covered by epidermal sheets “grown” from a small sample of intact skin from another part of the burn victim’s body. (We consider this treatment in the Clinical Note: Burns and Grafts.)

✓ Checkpoint

1. Identify the layers of the epidermis.
2. Dandruff is caused by excessive shedding of cells from the outer layer of skin on the scalp. So, dandruff is composed of cells from which epidermal layer?
3. A splinter that penetrates to the third layer of the epidermis of the palm is lodged in which layer?
4. Why does taking a bath cause wrinkly fingertips and toes?
5. Some criminals sand the tips of their fingers so as not to leave recognizable fingerprints. Would this practice permanently remove fingerprints? Why or why not?
6. Name the sources of epidermal growth factor in the body.
7. Identify some roles of epidermal growth factor related to the epidermis.

See the blue Answers tab at the back of the book.

5-2 The dermis is the tissue layer that supports the epidermis

Learning Outcome Describe the structures and functions of the dermis.

The dermis lies between the epidermis and the subcutaneous layer (**Figure 5-1**). Accessory structures of epidermal origin, such as hair follicles and sweat glands, extend into the dermis. In addition, the dermis contains networks of blood vessels and nerve fibers.

Layers of the Dermis

The dermis is made up of two major layers: (1) a superficial *papillary layer* and (2) a deeper *reticular layer*. The **papillary layer** consists of areolar tissue. It contains the capillaries, lymphatic vessels, and sensory nerve fibers that supply the surface of the skin. The papillary layer gets its name from the dermal papillae that project between the epidermal ridges (**Spotlight Figure 5-3a**).

Because of the abundance of sensory nerve endings and receptors in the skin, regional infection or inflammation of the skin can be very painful. **Dermatitis** (der-muh-TĪ-tis) is an inflammation of the skin that primarily involves the papillary layer. The inflammation typically begins in a part of the skin exposed to infection or irritated by chemicals, radiation, or mechanical stimuli. Dermatitis may cause no discomfort, or it may produce an annoying itch, as in poison ivy. Other forms of the condition can be quite painful, and the inflammation can spread rapidly across the entire integument.

The **reticular layer** lies deep to the papillary layer. It consists of an interwoven meshwork of dense irregular connective tissue containing both collagen and elastic fibers (**Figure 5-4**). Bundles of collagen fibers extend superficially beyond the reticular layer to blend into those of the papillary layer, so the boundary between the two layers is indistinct. Collagen fibers of the reticular layer also extend into the deeper subcutaneous layer. In addition to extracellular protein fibers, the dermis contains all the cells of connective tissue proper.

Dermal Strength and Elasticity

Collagen and elastic fibers give the dermis strength and elasticity. *Collagen fibers* are very strong and resist stretching, but they are easily bent or twisted. *Elastic fibers* permit stretching and then recoil to their original length. The elastic fibers provide flexibility, and the collagen fibers limit that flexibility to prevent damage to the tissue.

Figure 5-4 Reticular Layer of Dermis.

The water content of the skin also helps maintain its flexibility and resilience. These properties are collectively known as *skin turgor*. One of the signs of dehydration is the loss of skin turgor, revealed by pinching the skin on the back of the hand. A dehydrated dermis will remain peaked when pinched, but hydrated skin will flatten out.

Aging, hormones, and the destructive effects of UV radiation permanently reduce the amount of elastin in the dermis. Wrinkles and sagging skin result. The extensive distortion of the dermis that occurs over the abdomen during pregnancy or after substantial weight gain can exceed the elastic limits of the skin. The resulting damage to the dermis prevents it from recoiling to its original size after delivery or weight loss. The skin then wrinkles and creases, creating a network of **stretch marks**.

To treat reduced skin elasticity, *tretinoin* (a derivative of vitamin A) can be applied to the skin as a cream or gel. This drug was originally developed to treat acne, but it also increases

blood flow to the dermis and stimulates dermal repair. As a result, the rate of wrinkle formation decreases, and existing wrinkles become smaller. The degree of improvement varies among individuals.

Tension Lines

Most of the collagen and elastic fibers at any location are arranged in parallel bundles oriented to resist the forces applied to the skin during normal movement. The resulting pattern of fiber bundles in the skin establishes **tension lines**, also called *cleavage lines*. Tension lines are clinically significant, because a cut made parallel to a tension line will usually remain closed and heal with little scarring, whereas a cut made at right angles to a tension line will be pulled open as severed elastic fibers recoil, resulting in greater scarring. When possible, surgeons make incisions parallel to tension lines (**Figure 5-5**).

5

Figure 5-5 Tension Lines of the Skin. Tension lines follow the pattern of collagen fiber bundles in the dermis of the skin.

The Dermal Blood Supply

Arteries supplying the skin lie deep within the subcutaneous layer. Branches of these arteries form two networks, or *plexuses*, in the dermis. The deeper network lies along the border of the subcutaneous layer with the reticular layer of the dermis. This network is called the **cutaneous plexus** (**Figure 5-6**). Branches of these arteries supply both the adipose tissues of the subcutaneous layer and the tissues of the integument. As small arteries travel toward the epidermis, branches supply the hair follicles, sweat glands, and other structures in the dermis.

Figure 5-6 Dermal Circulation. The cutaneous and subpapillary plexuses are shown.

Which plexus supplies blood to the capillary loops that follow the epidermis–dermis boundary?

On reaching the papillary layer, the small arteries form another branching network, the **subpapillary plexus** (Figure 5-6). It provides arterial blood to capillary loops that follow the contours of the epidermis–dermis boundary. These capillaries empty into small veins of the subpapillary plexus, which drain into veins accompanying the arteries of the cutaneous plexus. This network in turn connects to larger veins in the subcutaneous layer.

Trauma to the skin often results in a *contusion*, or bruise. When dermal blood vessels rupture, blood leaks into the dermis, and the area develops the familiar “black and blue” color.

Innervation of the Skin

5

The integument is filled with sensory nerve fiber endings and sensory receptors. Anything that contacts the skin—from the lightest touch of a mosquito to the weight of a loaded backpack—initiates a nerve impulse that can reach our conscious awareness. Nerve fibers in the skin control blood flow, adjust glandular secretion rates, and monitor sensory receptors in the dermis and the deeper layers of the epidermis.

We have already noted that the deeper layers of the epidermis contain tactile discs. They are fine touch and pressure receptors. The epidermis also contains sensory nerve endings that provide sensations of pain and temperature. The dermis contains similar nerve endings, as well as other, more specialized receptors. Examples shown in Figure 5-1 include receptors sensitive to light touch—*tactile corpuscles* (*Meissner corpuscles*), located in dermal papillae—and receptors sensitive to deep pressure and vibration—*lamellar corpuscles* (*pacinian corpuscles*), in the reticular layer.

Even this partial list of the receptors in the skin is enough to highlight the importance of the integument as a sensory structure. We return to this topic in Chapter 15, where we consider not only what receptors are present, but also how they function.

Checkpoint

8. Describe the location of the dermis.
9. Where are the capillaries and sensory nerve fibers that supply the epidermis located?
10. What accounts for the ability of the dermis to undergo repeated stretching?

See the blue Answers tab at the back of the book.

5-3 The subcutaneous layer connects the dermis to underlying tissues

Learning Outcome Describe the structures and functions of the subcutaneous layer.

The **subcutaneous layer** (*hypodermis*) lies deep to the dermis (Figure 5-1). The boundary between the two is generally indistinct because the connective tissue fibers of the reticular layer are extensively interwoven with those of the subcutaneous

Figure 5-7 The Subcutaneous Layer.

layer. The subcutaneous layer is not a part of the integument, but it is important in stabilizing the position of the skin in relation to underlying tissues, such as skeletal muscles or other organs, while permitting independent movement.

The subcutaneous layer is quite elastic. It consists primarily of adipose tissue (areolar tissue dominated by adipocytes) (Figure 5-7). Also called subcutaneous fat, it makes up about 80% of all body fat. (The remaining amount is visceral fat that is associated with visceral organs.) Only the superficial region of the subcutaneous layer contains large arteries and veins. The venous circulation of this region contains a substantial amount of blood, and much of this volume will shift to the general circulation if these veins constrict. For that reason, we often describe the skin as a *blood reservoir*. The rest of the subcutaneous layer contains a limited number of capillaries and no vital organs. This last characteristic makes **subcutaneous injection**—by means of a **hypodermic needle**—a useful method of administering drugs.

Most infants and small children have extensive “baby fat,” which provides insulation and helps reduce heat loss. This subcutaneous fat also serves as a substantial energy reserve and as a shock absorber for the rough-and-tumble activities of our early years.

As we grow, the distribution of subcutaneous fat changes. The greatest changes take place in response to circulating hormones. Beginning at puberty, males build up subcutaneous fat at the neck, on the arms, along the lower back, and over the buttocks. In contrast, females accumulate subcutaneous fat at the breasts, buttocks, hips, and thighs. In adulthood, the subcutaneous layer of the backs of the hands and the upper surfaces of the feet contains few fat cells, but adipose tissue can accumulate in the abdominal region. An excessive amount of such abdominal fat, also called *central adiposity*, is strongly correlated with cardiovascular disease.

Clinical Note Nips, Tucks, and Shots

According to the American Society of Plastic Surgeons, millions of cosmetic procedures are performed every year in the United States. The most common cosmetic surgery sought by males is rhinoplasty (nose reshaping); for females it is breast augmentation.

Rhinoplasty changes the appearance of the nose or relieves breathing problems. Remodeling of bone and cartilage can be done through an open (external) incision or endonasally (inside the nose).

Breast augmentation and reconstruction following breast cancer surgery now use shaped implants made of silicone or saline that more closely resemble the look and feel of the natural breast. However, implants can make it harder to obtain a clear image of the breast during mammography screening.

“Nips and tucks” remove excess skin and underlying fat in the face, chin, back of the arm, belly, buttocks, and thighs. *Abdominoplasty* (tummy tuck) reduces loose abdominal skin after multiple pregnancies or significant weight loss. A visible scar remains across the lower abdomen. *Liposuction* removes subcutaneous adipose tissue through a tube inserted deep to the skin while the person is anesthetized. Liposuction might sound like an easy way to remove unwanted fat, but in practice, it can be dangerous. There are risks from anesthesia, and bleeding (adipose tissue is quite vascular), sensory deficits, infection, and fluid loss can also occur.

Other popular cosmetic procedures are minimally invasive and can be done in healthcare office-based settings. For example, millions of **botulinum toxin A** (Botox) shots are given annually to reduce wrinkles. Botox weakens muscles by blocking the signals from nerves to those muscles. **Dermal fillers**, such as calcium hydroxylapatite, hyaluronic acid, or collagen, are injected to plump up sagging skin. However, the effects of these fillers are short lived because the fillers are cleared by dermal macrophages.

Checkpoint

11. List the two terms for the tissue that connects the dermis to underlying tissues.
12. Describe the subcutaneous layer.
13. Identify several functions of subcutaneous fat.

See the blue Answers tab at the back of the book.

5-4 Epidermal pigmentation and dermal circulation influence skin color

Learning Outcome Explain what accounts for individual differences in skin color and discuss the response of melanocytes to sunlight exposure.

One of the most obvious distinguishing characteristics among humans is skin color. What gives skin its various colors? In this section we examine how pigments in the epidermis and blood flow in the dermis influence skin color. We also discuss clinical implications of changes in skin color.

The Role of Epidermal Pigmentation

The epidermis contains variable quantities of two pigments: melanin and carotene. Both pigments contribute to skin

color, but melanin, which is made in the skin, is the primary determinant.

Melanin

Melanin is a pigment produced by **melanocytes**, pigment-producing cells, introduced in Chapter 4. There are two types of melanin, a red-yellow form (pheomelanin) and a brown-black form (eumelanin). The melanocytes involved are located in the stratum basale, squeezed between or deep to the epithelial cells (**Figure 5–8**). Melanocytes manufacture both types of melanin from the amino acid *tyrosine* and package it into intracellular vesicles called *melanosomes*. These vesicles, which can contain either type of melanin, travel within the processes of melanocytes and are transferred intact to nearby basal keratinocytes. The transfer of pigment colors the keratinocytes temporarily, until the melanosomes are destroyed by fusion with lysosomes. In individuals with pale skin, this transfer takes place in the stratum basale and stratum spinosum, and the cells of more superficial layers lose their pigmentation. In dark-skinned people, the melanosomes are larger and more numerous, and the transfer may occur in the stratum granulosum as well, making skin pigmentation darker and more persistent.

Media resource available for this topic: Practice Anatomy Lab: Integumentary System: Histology

Figure 5–8 Melanocytes.

a This micrograph shows the location and orientation of melanocytes in the stratum basale of a dark-skinned person.

b Melanocytes produce and store melanin.

? In what layer of the skin are melanocytes found?

The ratio of melanocytes to basal cells ranges between 1:4 and 1:20, depending on the region of the body. The skin covering most areas of the body has about 1000 melanocytes per square millimeter. The cheeks and forehead, the nipples, and the genital region (the scrotum of males and the labia majora of females) have higher concentrations (about 2000 per square millimeter). The differences in skin pigmentation among individuals do not reflect different numbers of melanocytes, but rather different levels of melanin synthesis. A deficiency or absence of melanin production leads to a disorder known as *albinism*. Individuals with this condition have a normal

distribution of melanocytes, but the cells are incapable of producing melanin.

There can also be localized differences in the rates of melanin production by melanocytes. *Freckles* are small, pigmented areas on relatively pale skin. These spots typically have an irregular border. They represent the areas serviced by melanocytes that are producing larger-than-average amounts of melanin. Freckles tend to be most abundant on surfaces such as the face, probably due to its greater exposure to the sun. *Lentigos* are similar to freckles but have regular borders and contain abnormal melanocytes. *Senile lentigos*, or *liver spots*, are variably pigmented areas that develop on sun-exposed skin in older individuals with pale skin.

The melanin in keratinocytes protects the epidermis and dermis from the harmful effects of sunlight, which contains significant amounts of **ultraviolet (UV) radiation**. Melanocytes respond to UV exposure by increasing their production of melanin. A small amount of UV radiation is beneficial, because it stimulates the epidermis to produce a compound required for calcium ion homeostasis (a process discussed in a later section). However, UV radiation can also damage DNA, causing mutations and promoting the development of cancer. Within keratinocytes, melanosomes become concentrated in the region around the nucleus, where the melanin pigments act like a sunshade to provide some UV protection for the DNA in those cells.

UV radiation can also produce some immediate effects, such as burns. If severe, sunburns can damage both the epidermis and the dermis. Thus, the pigment layers in the epidermis help protect both epidermal and dermal tissues. However, the production of melanin is not rapid enough to prevent sunburn the first day spending time in the sun. Melanin synthesis accelerates slowly, peaking about 10 days after the initial exposure. Individuals of any skin color are at risk for sun damage to the skin, but dark-skinned individuals have greater initial protection.

Over time, cumulative UV damage to the skin can harm fibroblasts, impairing maintenance of the dermis. The result is premature wrinkling. In addition, skin cancers can develop from chromosomal damage in basal cells or melanocytes.

Carotene

Carotene (KAR-uh-tēn) is an orange-yellow pigment that normally accumulates in epidermal cells. It is most apparent in cells of the stratum corneum of light-skinned individuals, but it also accumulates in fatty tissues in the deep dermis and subcutaneous layer. Carotene is also found in a variety of orange vegetables, such as carrots and squashes. The skin of someone who eats lots of carrots can turn orange from an overabundance of carotene. The color change is very striking in pale-skinned individuals, but less obvious in people with

darker skin pigmentation. Carotene can be converted to vitamin A, which is required for both the normal maintenance of epithelia and the synthesis of photoreceptor (light receptor) pigments in the eye.

The Role of Dermal Circulation: Hemoglobin

Blood contains red blood cells filled with the pigment *hemoglobin*, which binds and transports oxygen in the bloodstream. When bound to oxygen, hemoglobin is bright red, giving capillaries in the dermis a reddish tint that is most apparent in lightly pigmented individuals. If those vessels are dilated, the red tones become much more pronounced in areas like cheeks and gums. Body temperature rises because the superficial blood vessels dilate so that the skin surface can act like a radiator and lose heat.

The skin and gums become relatively pale when their blood supply is temporarily reduced. During a sustained reduction in blood supply, the oxygen level in tissues decreases. Under these conditions, hemoglobin releases oxygen and turns a much darker red. Seen from the surface, the skin, mucous membranes, lips, gums, whites of the eyes, and nail beds appear pale and bluish. This bluish coloration is known as **cyanosis** (sī-uh-NŌ-sis; *kyanos*, blue). It can also occur in response to extreme cold or as a result of cardiovascular or respiratory disorders, such as heart failure or severe asthma.

Disease-Related Changes in Skin Color

Because the skin is easy to observe, changes in the skin's appearance can be useful in diagnosing diseases that primarily affect other body systems. Several diseases can produce secondary effects on skin color and pigmentation:

- In *jaundice* (JAWN-dis), the liver is unable to excrete bile, so a yellowish pigment accumulates in body fluids. In advanced stages, the skin and whites of the eyes turn yellow.
- Some tumors affecting the pituitary gland result in the secretion of large amounts of *melanocyte-stimulating hormone* (MSH). This hormone causes melanocytes to overproduce melanin, leading to a darkening of the skin, as if the person has an extremely deep bronze tan.
- In *Addison's disease*, the pituitary gland secretes large quantities of *adrenocorticotrophic hormone* (ACTH), which is structurally similar to MSH. The effect of ACTH on skin color is also similar to that of MSH.
- In *vitiligo* (vit-i-LĪ-gō), individuals lose their melanocytes, causing white patches on otherwise normal skin (**Figure 5-9**). The condition develops in about 1% of the population. Its incidence increases among individuals with thyroid gland disorders, Addison's disease, or several other disorders. It is suspected that vitiligo develops

Figure 5-9 Vitiligo.

when the immune defenses malfunction and antibodies attack normal melanocytes. There are no serious health effects associated with vitiligo; however, people with the condition may have hearing loss and are at increased risk of sunburns.

✓ Checkpoint

14. Name the two major pigments in the epidermis.
15. Why does exposure to sunlight darken skin?
16. What areas appear bluish in individuals who have decreased blood oxygen levels?

See the blue Answers tab at the back of the book.

5-5 Sunlight causes epidermal cells to convert a steroid into vitamin D₃

Learning Outcome Describe the interaction between sunlight and vitamin D₃ production.

Too much sunlight can damage epithelial cells and deeper tissues, but limited exposure to sunlight is beneficial. When exposed to UV radiation, epidermal cells in the stratum spinosum and stratum basale convert a cholesterol-related steroid compound into *cholecalciferol* (kō-le-kal-SIF-er-ol), or **vitamin D₃**. The liver then converts cholecalciferol into an intermediary product used by the kidneys to synthesize the hormone **calcitriol** (kal-si-TRĪ-ol) (**Figure 5-10**). Calcitriol is essential for the normal absorption of calcium and phosphate ions in the small intestine. An inadequate supply leads to impaired bone maintenance and growth.

The term *vitamin* is usually reserved for essential organic nutrients that we must get from the diet because the body either makes them in insufficient amounts or not at all. Cholecalciferol can be absorbed by the digestive tract, and if the skin cannot make enough cholecalciferol, a dietary supply

+ Clinical Note Skin Cancer

Almost everyone has several *benign* (be-NĪN; noncancerous) tumors of the skin. Moles and warts are common examples. However, skin cancers, which can be dangerous, are the most common form of cancer.

An *actinic keratosis*, a precancerous scaly area on the skin, is an indication that sun damage has occurred. In untreated individuals, it can lead to squamous cell carcinoma. In contrast, *basal cell carcinoma*, a cancer that originates in the stratum basale is the most common skin cancer (**Photo a**). About two-thirds of these cancers appear in body areas subjected to chronic UV exposure. Researchers have identified genetic factors that predispose people to this condition. *Squamous cell carcinomas* are less common but are almost totally restricted to areas of sun-exposed skin. *Metastasis* (spread to distant body sites) seldom occurs in treated squamous cell and basal cell carcinomas, and most people survive these cancers. The usual treatment involves the surgical removal of the tumor, and 95% of patients survive for 5 years or longer after treatment. (This statistic, the *5-year survival rate*, is a common method of reporting long-term outcomes.)

Unlike these common and seldom life-threatening cancers, *malignant melanomas* (mel-ah-NŌ-muz) are extremely dangerous (**Photo b**). In this condition, cancerous melanocytes grow rapidly and metastasize through the lymphatic system and/or blood vessels. The outlook for long-term survival is in many cases determined by how early the

condition is diagnosed. If the cancer is detected early, while it is still localized, the 5-year survival rate is 99%. If it is not detected until extensive metastasis has occurred, the survival rate drops to 14%.

To detect melanoma at an early stage, the skin must be examined and the signs recognized. The mnemonic ABCDE makes it easy to remember this cancer's key characteristics:

- **A** is for *asymmetry*: One half of a melanoma is unlike the other half. Typically, they are raised; they may also ooze or bleed.
- **B** is for *border*: The border of a melanoma is generally irregular, and in some cases notched.
- **C** is for *color*: A melanoma is generally mottled, with any combination of tan, brown, black, red, pink, white, and blue tones.
- **D** is for *diameter*: Melanomas are usually more than 6 mm in diameter, or approximately the area covered by a pencil eraser.
- **E** is for *evolving*: Benign lesions look the same over time. Any change in size, shape, or color signals possible melanoma.

Prevent sun damage by avoiding exposure to the sun during the middle of the day and by using a sunscreen (not tanning oils, lotions, or accelerators) before any sun exposure. This practice also delays the cosmetic problems of aging and wrinkling. *Everyone*, regardless of skin color, should choose a broad-spectrum sunscreen with a sun protection factor (SPF) of at least 15 because people of all colors can get skin cancer. The protection offered by these sunscreens comes both from organic molecules that absorb UV radiation and from inorganic pigments that absorb, scatter, and reflect UV rays. The higher the SPF, the more of these chemicals the product contains; hence, fewer UV rays can penetrate to the skin's surface. Wearing a hat with a brim and panels to shield the neck and face, long pants, and long-sleeved shirts provides added protection.

The use of sunscreens is also important while ozone gas in the upper atmosphere is destroyed by our industrial emissions. Ozone absorbs UV radiation before it reaches Earth's surface. In doing so, ozone assists the melanocytes in preventing skin cancer.

a Basal cell carcinoma

b Melanoma

(from foods such as egg yolks, fish oil, and fortified milk) will maintain normal bone development. Under these circumstances, dietary cholecalciferol acts like a vitamin. For this reason, cholecalciferol is also called *vitamin D₃*.

If cholecalciferol cannot be produced by the skin and is not included in the diet, bone development is abnormal and bone maintenance is inadequate. For example, children who

live in areas with overcast skies and whose diet lacks cholecalciferol can have abnormal bone development. This condition, called **rickets** (**Figure 5-11**), has largely been eliminated in the United States because dairy companies are required to add cholecalciferol, usually identified as "vitamin D," to the milk sold in grocery stores. In Chapter 6, we consider the hormonal control of bone growth in greater detail.

Figure 5–10 Sources of Vitamin D₃.

What are the body's two sources of cholecalciferol (vitamin D₃)?

Figure 5–11 Rickets. Rickets, a disease caused by vitamin D₃ deficiency, results in the bending of abnormally weak and flexible bones under the weight of the body, plus other structural changes.

✓ Checkpoint

17. Explain the relationship between sunlight exposure and vitamin D₃ synthesis.
18. In some cultures, women must be covered completely, except for their eyes, when they go out in public. Explain why these women may develop bone problems later in life.

See the blue Answers tab at the back of the book.

5-6 Hair is made of keratinized dead cells pushed to the skin surface, where it has protecting and insulating roles

Learning Outcome Describe the mechanisms that produce hair and explain the structural basis for hair texture and color.

Hair and several other structures—hair follicles, sebaceous and sweat glands, and nails—are considered accessory structures of the integument. During embryonic development, these structures originate from the epidermis, so they are also known as *epidermal derivatives*. Although located in the dermis, they project to the surface of the skin.

Hair projects above the surface of the skin almost everywhere, except over the sides and soles of the feet, the palms of the hands, the sides of the fingers and toes, the lips, and portions of the external genitalia. Humans have about 2.5 million hairs, and 75% of them are on the general body surface, not on the head. Hairs are nonliving structures produced in organs called **hair follicles**.

The hairs and hair follicles on the body have important functions. The 500,000 or so hairs on the head protect the scalp from ultraviolet radiation, help cushion light impacts to the head, and insulate the skull. The hairs guarding the entrances to the nostrils and external ear canals help keep out foreign particles and insects. The eyelashes do the same for the surfaces of the eyes. Eyebrows are important because they help keep sweat out of the eyes. Hairs also play a critical role as sensory receptors.

Hair and Hair Follicle Structure

Figure 5–12 illustrates important details about the structure of hairs and hair follicles. Each hair follicle opens onto the surface of the epidermis but extends deep into the dermis and usually into the hypodermis. Deep to the epidermis, each follicle is wrapped in a dense connective tissue sheath. A **root hair plexus** of sensory nerves surrounds the base of each hair follicle (**Figure 5–12a**). As a result, movement of a single hair shaft can be felt. This sensitivity provides an early-warning system that may help prevent injury. For example, a mosquito may be swatted before it reaches the skin surface.

+ Clinical Note Decubitus Ulcers

Problems with dermal circulation affect both the epidermis and the dermis. An *ulcer* is a localized area where the epithelium has been eroded. *Decubitus* (dē-KYŪ-bih-tus) *ulcers*, also called *bedsores*, affect patients whose circulation is restricted, especially when a splint, a cast, or lying in bed continuously compresses superficial blood vessels. Such sores most commonly affect the skin covering joints or bony prominences, where dermal blood vessels are pressed against deeper structures. The chronic lack of circulation kills epidermal cells, removing a barrier to bacterial infection. Eventually, dermal tissues deteriorate as well. The prevention and care of bedsores is an expertise of nursing. Prevention entails frequently changing the patient's position and using pressure-relieving mattresses in hospital settings. Treatment involves the use of hyperbaric (high-pressure) oxygen to deliver maximum oxygen to blood traveling through compressed tissues.

5

A bundle of smooth muscle cells forms the **arrector pili** (a-REK-tor PĪ-lī) **muscle**, also called *arrector muscle of hair*. It extends from the papillary layer of the dermis to the connective tissue sheath surrounding the hair follicle. When stimulated, the arrector pili muscle contracts, pulling on the follicle and forcing the hair to stand erect. Contraction may be the result of emotional states, such as fear or rage, or a response to cold, producing “goose bumps.” In a furry mammal, this action increases the thickness of its insulating coat. Humans do not receive any comparable insulating benefits, but the response persists.

Each hair is a long, cylindrical structure that extends outward, past the epidermal surface (**Figure 5–12a**). The **hair root** is the portion that anchors the hair into the skin. The root begins at the base of the hair, at the *hair bulb*, and extends distally to the point at which the internal organization of the hair is complete, about halfway to the skin surface. The **hair shaft** extends from this halfway point to the exposed tip of the hair. The visible hair is the protruding part of the hair shaft.

Seen in cross section, a hair has three layers (**Figure 5–12b**). The cells in the core of the hair make up what is called the **medulla**. Cells farther from the center of the hair matrix form the **cortex**, an intermediate layer. Those at the edges of the hair matrix form the **cuticle**, which will be the surface of the hair.

Around the hair, the epithelial cells of the follicle walls are organized into several concentric layers. Moving outward from the hair cuticle, these layers include the *internal root sheath*, the *external root sheath*, and the *glassy membrane* (**Figure 5–12b**).

Hair Production

Hair production begins at the bulging base of a hair follicle, a region called the **hair bulb** (**Figure 5–12c, d**). The hair bulb surrounds a small **hair papilla**, a peg of connective tissue containing capillaries and nerves. A layer of epithelial cells at the base of the hair bulb in contact with the hair papilla produces the hair. This layer is called the **hair matrix**. Basal cells of the hair matrix divide, producing daughter cells that are gradually pushed toward the surface. Depending on the location of these daughter cells, they then form the medulla, cortex, and cuticle of the hair.

As cell divisions continue at the hair matrix, the daughter cells are pushed toward the surface of the skin, and the hair gets longer. Keratinization is completed by the time these cells approach the surface. At the level that corresponds to the start of the hair shaft, the cells of the medulla, cortex, and cuticle are dead, and the keratinization process is at an end.

The Hair Growth Cycle

Hairs grow and are shed according to a **hair growth cycle**. A hair in the scalp grows for 2 to 5 years, at a rate of about 0.33 mm per day. Variations in the growth rate and in the duration of the hair growth cycle account for individual differences in the length of uncut hair.

While hair is growing, the cells of the hair root absorb nutrients and incorporate them into the hair structure. As a result, clipping or collecting hair for analysis can be helpful in diagnosing several disorders. For example, hairs of individuals with lead poisoning or other heavy metal poisoning contain high levels of those metal ions. Hair samples containing nucleated cells can also be used for identification purposes through DNA fingerprinting.

As a hair grows, the root is firmly attached to the matrix of the follicle. At the end of the growth cycle, the follicle becomes inactive. The hair is now termed a **club hair**. The follicle gets smaller, and over time the connections between the hair matrix and the club hair root break down. When another cycle begins, the follicle produces a new hair. The old club hair is pushed to the surface and is shed.

Healthy adults with a full head of hair typically lose about 100 head hairs each day. Sustained losses of more than 100 hairs per day generally indicate that a net loss of hairs is under way, and hair loss will eventually be noticeable. Temporary increases in hair loss can result from drugs, dietary factors, radiation, an excess of vitamin A, high fever, stress, or hormonal factors related to pregnancy.

Figure 5–12 Hair Follicles and Hairs.

In males, changes in circulating hormone levels in the blood can affect the scalp, causing a shift in the type of hair produced (discussed shortly), beginning at the temples and the crown of the head. This alteration is called *male pattern baldness*. Some cases of male pattern baldness respond to drug therapies, such as the topical application of *minoxidil* (*Rogaine*).

Types of Hairs

Hairs first appear after about 3 months of embryonic development. These hairs, collectively known as *lanugo* (la-NŪ-gō), are extremely fine and unpigmented. Most lanugo hairs are shed before birth.

5

They are replaced by one of two types of hairs in the adult integument: vellus hairs or terminal hairs. **Vellus hairs** are the fine “peach fuzz” hairs located over much of the body surface. **Terminal hairs** are heavy, more deeply pigmented, and sometimes curly. The hairs on the head, including the eyebrows and eyelashes, are terminal hairs that are present throughout life. However, in other areas hair follicles may alter the type of the hairs produced in response to circulating hormones. For example, vellus hairs are present at the armpits, pubic area, and limbs until puberty. After puberty, the follicles produce terminal hairs, in response to circulating hormones.

What makes hair curly or straight? The cross-sectional shape of the hair shaft and its hair follicle determine whether hairs are curly or straight. A curly hair and its follicle are oval; a straight hair and its follicle are round.

Tips

Associate the word *vellus* (“peach fuzz”) with “velvet.”

Hair Color

What gives hair its color? Variations in hair color reflect differences in structure and variations in the pigment produced by melanocytes at the hair matrix. Different forms and amounts of melanin give a black, dark brown, yellow-brown, or red color to hair. Genes determine these structural and biochemical characteristics, but hormonal and environmental factors also influence the condition of hair.

As pigment production decreases with age, hair color lightens. White hair results from the combination of a lack of pigment and the presence of air bubbles in the medulla of the hair shaft. As the proportion of white hairs increases, the person’s overall hair color is described as gray or even white. Because hair itself is dead and inert, any changes in its coloration are gradual.

What happens when hair is dyed? Hair color can be changed by using chemicals that disrupt the cuticle and permit dyes to enter and stain the cortex and medulla. These color treatments damage the hair’s protective cuticle layer

and dehydrate and weaken the hair shaft. As a result, the hair becomes thinner and brittle. Conditioners and oil treatments attempt to reduce the effects of this structural damage by rehydrating and recoating the shaft.

Checkpoint

19. Describe a typical strand of hair.
20. What happens when the arrector pili muscle contracts?
21. Once a burn on the forearm that destroys the epidermis and extensive areas of the deep dermis heals, will hair grow again in the affected area?

See the blue Answers tab at the back of the book.

5-7 Sebaceous glands and sweat glands are exocrine glands found in the skin

Learning Outcome Discuss the various kinds of glands in the skin and list the secretions of those glands.

As shown previously, the integumentary system contains various accessory structures that produce exocrine secretions. In this section we focus on the structure and function of sebaceous glands and sweat glands.

Sebaceous Glands

Sebaceous (se-BĀ-shus) **glands**, or *oil glands*, are holocrine glands that discharge an oily lipid secretion into hair follicles (**Figure 5-13**). The gland cells produce large quantities of these lipids, called **sebum** (SĒ-bum), as they mature. These glands release the sebum through holocrine secretion, a process that involves the rupture of the secretory cells. Sebaceous glands that communicate with a single hair follicle share a duct and thus are classified as simple branched alveolar glands.

The sebum released from gland cells enters the lumen (open passageway around the hair) of the gland. The arrector pili muscles that erect the hair then contract, squeezing the sebaceous gland and forcing the sebum into the hair follicle and onto the surface of the skin. Sebum is a mixture of triglycerides, cholesterol, proteins, and electrolytes. It inhibits bacterial growth, lubricates and protects the hair shaft, and conditions the surrounding skin. The hair shaft is made of keratin, which is a tough protein, but dead, keratinized cells become dry and brittle once exposed to the environment. Interestingly, when we shampoo and wash, we remove the oily secretions of sebaceous glands, only to add other lipids to our hair in the form of conditioners, and to our skin in the form of creams and lotions.

Sebaceous follicles are large sebaceous glands that are not associated with hair follicles. Instead, their ducts discharge sebum directly onto the epidermis (**Figure 5-13**). We have

Figure 5–13 The Structure of Sebaceous Glands and Sebaceous Follicles.

Where do sebaceous glands and sebaceous follicles discharge their secretions?

sebaceous follicles on the face, back, chest, nipples, and external genitalia.

Sebaceous glands are very active during the last few months of fetal development. Their secretions, mixed with shed epidermal cells, form a protective superficial layer—the *vernix caseosa*—that coats the skin surface. Sebaceous gland activity all but stops after birth, but it increases again at puberty in response to rising hormone levels.

Seborrheic (seb-ō-RE-ik) *dermatitis* is an inflammation around abnormally active sebaceous glands, most often in the scalp. The affected area becomes red and oily, with increased epidermal scaling. In infants, mild cases are called *cradle cap*. Seborrheic dermatitis is a common cause of dandruff in adults. Anxiety, stress, and fungal or bacterial infections can aggravate the problem.

Sweat Glands

The skin contains two types of **sweat glands**, or *sudoriferous glands* (*sudor*, sweat): *apocrine sweat glands* and *eccrine sweat glands* (Figure 5–14).

Apocrine Sweat Glands

In the armpits, around the nipples, and in the pubic region, **apocrine sweat glands** secrete their products into hair follicles (Figure 5–14a). These coiled, tubular glands produce a sticky, cloudy, and potentially odorous secretion. The name *apocrine* was originally chosen because it was thought the gland cells

used an apocrine method of secretion. We now know that they rely on merocrine secretion, but the name has not changed.

Apocrine sweat glands begin secreting at puberty. This sweat is a nutrient source for bacteria, whose growth and breakdown intensify its odor. Surrounding the secretory cells in these glands are special myoepithelial cells that contract and squeeze the gland, causing the accumulated sweat to discharge into the hair follicles. The secretory activities of the gland cells and the contractions of myoepithelial cells are controlled by the nervous system and by circulating hormones.

Eccrine Sweat Glands

Eccrine (EK-rin) **sweat glands** are also known as *merocrine sweat glands*. These coiled, tubular glands discharge their secretions directly onto the surface of the skin (Figure 5–14b). Eccrine sweat glands are far more numerous and widely distributed than apocrine sweat glands. The adult integument contains 2–5 million eccrine sweat glands, which are smaller than apocrine sweat glands and do not extend as deeply into the dermis. The palms and soles have the highest numbers; the palms have an estimated 500 eccrine sweat glands per square centimeter (3000 per square inch).

As noted earlier, the sweat from eccrine sweat glands is called sensible perspiration. Sweat is 99% water, but it also contains some other components, including sodium chloride, which gives sweat a salty taste. It has a pH range of 4.0–6.8. (See Appendix A, Table 1 for a complete analysis of the composition of normal sweat.)

Figure 5–14 Sweat Glands.

The functions of eccrine sweat glands include the following:

- **Cooling the Surface of the Skin to Reduce Body Temperature.** This is the primary function of sensible perspiration. The degree of secretory activity is regulated by neural and hormonal mechanisms. When all the eccrine sweat glands are working at their maximum, we can perspire more than a gallon per hour, and dangerous fluid and electrolyte losses can occur. For this reason, athletes in endurance sports must drink fluids at regular intervals.
- **Excreting Water and Electrolytes.** Water, salts (mostly sodium chloride), and metabolized drugs are excreted.
- **Providing Protection from Environmental Hazards.** Sweat dilutes harmful chemicals in contact with the skin. It also discourages the growth of microorganisms in two ways: (1) by either flushing them from the surface or making it difficult for them to adhere to the epidermal surface and (2) through the action of *dermicidin*, a small peptide with powerful antibiotic properties.

The armpits provide consistent heat and moisture, ideal conditions for bacterial growth on the body surface. Deodorants and antiperspirants, singly or in combination, are commonly used to combat underarm bacteria and odor. Deodorants work by temporarily reducing bacteria numbers and by masking the body odor they produce. Antiperspirants target the sweat glands. Antiperspirants contain aluminum compounds that reduce the amount of moisture available to bacteria in two ways: (1) They interact with sweat to plug up sweat gland ducts, and (2) they cause the sweat gland pores to constrict. However, the plugs are eventually lost through the normal shedding of cells at the skin surface.

Other Integumentary Glands

As noted previously, sebaceous glands are located wherever there are hair follicles, apocrine sweat glands are in relatively restricted areas, and eccrine sweat glands are widely distributed across the body surface. The skin also contains a variety of specialized glands that are restricted to specific locations. Here are two important examples:

1. The **mammary glands** of the breasts are anatomically related to apocrine sweat glands. A complex interaction between sex hormones and pituitary hormones controls their development and secretion. Mammary gland structure and function is described in Chapter 28.
2. **Ceruminous** (se-RŪ-mi-nus) **glands** are modified sweat glands in the passageway of the external ear. Their secretions combine with those of nearby sebaceous glands, forming a mixture called **cerumen**, or earwax. Together with tiny hairs along the ear canal, earwax helps trap foreign particles, preventing them from reaching the eardrum.

Control of Glandular Secretions and Thermoregulation

The autonomic nervous system (ANS) is the portion of the nervous system that adjusts our basic life support systems without our conscious control. It controls the activation and deactivation of sebaceous glands and apocrine sweat glands. Regional control is not possible. The commands from the ANS affect all the glands of that type, everywhere on the body surface.

Eccrine sweat glands are much more precisely controlled, and the amount of secretion and the area of the body involved

can vary independently. For example, when nervously awaiting an anatomy and physiology exam, only the palms may begin to sweat.

As we noted earlier, the primary function of sensible perspiration is to cool the surface of the skin and to reduce body temperature. When the environmental temperature is high, this is a key component of *thermoregulation*, the homeostatic process of maintaining temperature. Remember that Chapter 1 introduced the negative feedback mechanisms of thermoregulation. When sweating in the hot sun, all eccrine glands are working together. The blood vessels beneath the epidermis are dilated and filled with blood. On lighter skin tones, affected areas show a visible reddening, although on darker skin tones, affected areas may show discoloration or darkening. The skin surface is also warm and wet, and as the moisture evaporates, the skin cools. If body temperature then decreases below normal, sensible perspiration stops, blood flow to the skin is reduced, and the skin surface cools and dries, releasing little heat into the environment.

✓ Checkpoint

22. Identify two types of exocrine glands found in the skin.
23. What are the functions of sebaceous secretions?
24. Deodorants are used to mask the effects of secretions from which type of skin gland?
25. Which type of skin gland is most affected by the hormonal changes that occur during puberty?

See the blue Answers tab at the back of the book.

5-8 Nails are keratinized epidermal cells that protect the tips of fingers and toes

Learning Outcome Describe the anatomical structures of nails and explain how they are formed.

Nails protect the exposed dorsal surfaces of the tips of the fingers and toes (**Figure 5-15a**). They also help limit distortion of the digits from mechanical stress—for example, when running barefoot or grasping objects. The **nail body**, the visible portion of the nail, covers an area of epidermis called the **nail bed** (**Figure 5-15b**). The nail body is recessed deep to the level of the surrounding epithelium and is bordered on either side by **lateral nail grooves** (depressions) and **lateral nail folds**. The **free edge** of the nail—the distal portion that continues past the nail bed—extends over the **hyponychium** (hī-pō-NIK-ē-um), an area of thickened stratum corneum (**Figure 5-15c**).

Nail production takes place at the **nail root**, an epidermal fold not visible from the surface. The deepest portion of the nail root lies very close to the bone of the fingertip. A portion of the stratum corneum of the nail root extends over the exposed nail, forming the **eponychium** (ep-ō-NIK-ē-um; *epi-*, over + *onyx*, nail), or **cuticle**. Underlying blood vessels give the

Figure 5-15 The Structure of a Nail.

nail its characteristic pink color. Near the root, these vessels may be obscured, leaving a pale crescent known as the **lunula** (LŪ-nū-luh; *luna*, moon) (**Figure 5-15a**).

The body of the nail consists of dead, tightly compressed cells packed with keratin. The cells producing the nails can be affected by conditions that alter body metabolism, so changes in the shape, structure, or appearance of the nails can provide useful diagnostic information. For example, the nails may turn yellow in individuals who have chronic respiratory disorders, thyroid gland disorders, or AIDS. Nails may become pitted and distorted because of *psoriasis* (so-RĪ-a-sis), a condition marked by rapid stem cell division in the stratum basale. Concave nails can result with some blood disorders.

✓ Checkpoint

26. What substance hardens fingernails?
27. What term is used to describe the thickened stratum corneum underlying the free edge of a nail?
28. Where does nail growth take place?

See the blue Answers tab at the back of the book.

5-9 After an injury, the integument is repaired in several phases

Learning Outcome Explain how the skin responds to injury and repairs itself.

The integumentary system can function semi-independently. It often responds directly and automatically to local influences without the involvement of the nervous or endocrine systems. For example, when the skin is continually subjected to mechanical stresses, stem cells in the stratum basale divide more rapidly, and the thickness of the epithelium increases. That is why calluses may develop on the soles of the feet and palms of the hand when exercising or working.

5

A more dramatic display of local regulation is obvious after an injury to the skin. The skin can regenerate effectively, even after considerable damage, because stem cells persist in both the epithelial and connective tissue. Basal cell divisions replace lost epidermal cells, and mesenchymal cell divisions replace lost dermal cells.

The process can be slow. When large surface areas are involved, infection and fluid loss complicate the situation. The speed and effectiveness of skin repair vary with the type of wound. For example, a slender, straight cut, or *incision*, may heal quickly compared with a deep scrape, or *abrasion*, which involves repairing a much greater surface area.

Figure 5-16 illustrates the four phases in the regeneration of the skin after an injury: inflammation, migration, proliferation, and scarring.

When damage extends through the epidermis and into the dermis, bleeding, along with swelling, redness, and pain occur. Mast cells in the region trigger an inflammatory response. This is the *inflammation phase* ①.

A dried blood clot, or **scab**, forms at the surface as part of the *migration phase* ②. The scab temporarily restores the integrity of the epidermis and restricts the entry of additional microorganisms into the area.

The bulk of the clot consists of an insoluble network of *fibrin*, a fibrous protein that forms from blood proteins during the clotting response. The clot's color is due to trapped red blood cells.

If the wound occupies an extensive area or involves a region covered by thin skin, dermal repairs must be under way before epithelial cells can cover the surface. Divisions by fibroblasts and mesenchymal cells produce mobile epithelial cells

Figure 5-16 Repair of Injury to the Integument.

that invade the deeper areas of injury. Endothelial cells of damaged blood vessels also begin to divide, and capillaries follow the fibroblasts, enhancing circulation. Phagocytic cells such as macrophages remove wastes from the area. The combination of blood clot, fibroblasts, and an extensive capillary network at the wound base is called **granulation tissue**.

Over time, deeper portions of the clot dissolve, and the number of capillaries declines in the *proliferation phase* ③. Fibroblasts produce a collagen fiber meshwork, the proliferation mentioned in the title of this phase. The repairs do not restore the integument to its original condition, however, because the dermis will contain an abnormally large number of collagen fibers and a few blood vessels. Severely damaged hair follicles, sebaceous or sweat glands, muscle cells, and nerves are seldom repaired. They, too, are replaced by fibrous tissue.

In the *scarring phase*, the formation of rather inflexible, fibrous, noncellular **scar tissue** completes the repair process, but without restoring the tissue to its original condition ④.

We do not know what regulates the extent of scar tissue formation, and the process is highly variable. For example, surgical procedures performed on a fetus do not leave scars, perhaps because damaged fetal tissues do not produce the same types of growth factors that adult tissues do. In some adults, most often those with dark skin, scar tissue formation may continue beyond the requirements of tissue repair. The result is a thickened mass of scar tissue that begins at the site of injury and grows into the surrounding dermis. This thick, raised area of scar tissue, called a **keloid** (KĒ-loyd), is covered by a shiny, smooth epidermal surface (Figure 5-17). Keloids can develop anywhere on the body where the tissue has been injured, including surgical sites. They are harmless and considered by some to be a cosmetic problem. However, some keloids are intentional, and some cultures produce keloids as a form of body decoration.

Figure 5-17 A Keloid. Keloids are areas of raised fibrous scar tissue.

People around the world adorn the skin with culturally significant markings of one kind or another. Tattoos, piercings, keloids and other scar patterns, and makeup are all used to “enhance” the appearance of the integument. Tattooing methods vary, but all involve using a sharp instrument to prick the skin and insert the pigment deep within the dermis. Because the pigment is inert, the markings remain for life, clearly visible through the overlying epidermis. Some of the risks associated with tattooing include allergic reactions, blood-borne infections from the use of contaminated equipment, and skin infections.

Tattoos can now be partially or completely removed by minimally invasive surgery, laser surgery, and dermabrasion. Laser surgery removal takes time (10 or more sessions may be required to remove a large tattoo), and scars often remain. To remove a tattoo using laser surgery, an intense, narrow beam of light from the laser breaks down the ink molecules in the dermis. Each blast of the laser that destroys the ink also burns the surrounding dermal tissue. Although the burns are minor, they accumulate and form localized scar tissue.

✓ Checkpoint

29. What term describes the combination of fibrin clots, fibroblasts, and the extensive network of capillaries in healing tissue?
30. Why can skin regenerate effectively even after considerable damage?

See the blue Answers tab at the back of the book.

Clinical Note The Skin, Mirror of Health

Changes in skin color, tone, and overall condition commonly reveal disease. Such changes can assist in diagnosing conditions involving other systems. A *contusion*, or bruise, for example, is a swollen, discolored area where blood has leaked through vessel walls. Extensive bruising without any obvious cause may indicate a blood-clotting disorder. Yellowish skin and mucous membranes may signify jaundice, which generally indicates some type of liver disorder. The general condition of the skin can also be significant. In addition to color changes, changes in the flexibility, elasticity, dryness, or sensitivity of the skin commonly follow malfunctions in other organ systems.

Clinical Note Burns and Grafts

Burns are common injuries that result from skin exposure to heat, friction, radiation, electrical shock, or strong chemical agents. In evaluating burns in a clinical setting, two key factors must be determined: the depth of the burn and the percentage of skin surface area that has been burned.

Classification by Depth of Burn

Partial-Thickness Burns

In a **first-degree burn** or *partial-thickness burn*, only the surface of the epidermis is damaged. In this type of burn, which includes most sunburns, the skin is tender and can be painful because of inflammation.

In a **second-degree burn** or *partial-thickness burn*, the entire epidermis and perhaps some of the dermis are damaged. Hair follicles and glands are usually not affected, but blistering, pain, and swelling occur. If the blisters rupture, infection can easily develop. Healing typically takes one to two weeks, and some scar tissue may form.

Full-Thickness Burns

Third-degree burns, or *full-thickness burns*, destroy the epidermis and dermis, extending into the subcutaneous layer. Despite swelling, these burns are less painful than second-degree burns, because sensory nerves are destroyed. These burns cannot repair themselves, because granulation tissue cannot form and epithelial cells cannot cover the injury site. *Skin grafting* is usually necessary.

Estimation of Surface Burn Area

A simple method for estimating burn area is the **rule of nines**. The surface area in adults is divided into multiples of 9 and then the damaged regions are totaled. This rule is modified for children because their body proportions are different.

The depth of the burn can be assessed quickly with a pin. Because loss of sensation indicates a full-thickness burn, no reaction to a pin prick indicates a third-degree burn.

Burns and Skin Function

Burns that cover more than 20 percent of the skin surface threaten life, because they affect the following functions.

Skin Functions Affected by Burns

- **Fluid and Electrolyte Balance.** Fluid and electrolytes are lost because the skin is no longer an effective barrier. In second-degree burns, fluid loss may reach five times the normal level.
- **Thermoregulation.** Increased fluid loss causes increased cooling by evaporation. As a result, more energy must be used to maintain normal body temperature.
- **Protection from Infection.** Widespread infection (*sepsis*) can result. Infection is the leading cause of death in burn victims.

Skin Grafts

In a **skin graft**, areas of intact skin are transplanted to cover the site of the burn. A *split-thickness graft* involves a transfer of the epidermis and superficial portions of the dermis. A *full-thickness graft* involves the epidermis and both layers of the dermis.

5-10 Effects of aging on the skin include thinning, wrinkling, and reduced melanocyte activity

Learning Outcome Summarize the effects of aging on the skin.

Aging affects all the components of the integumentary system:

- The epidermis thins as basal cell activity declines. The connections between the epidermis and dermis weaken, making older people more prone to skin injury, tears, and infections.
- The number of dendritic cells (Langerhans cells) decreases to about one-half the levels of a 21-year-old person. This decrease may reduce the sensitivity of the immune system and further encourage skin damage and infection.
- Vitamin D₃ production declines by about 75%. The result can be reduced calcium ion and phosphate ion absorption, eventually leading to muscle weakness and a reduction in bone strength and density.
- Melanocyte activity declines. With less melanin in the skin, people become more sensitive to sunlight and more likely to experience sunburn.
- Glandular activity declines. The skin becomes dry and often scaly because sebum production is reduced. Eccrine sweat glands are also less active. With impaired perspiration, older people cannot lose heat as fast as younger people, resulting in a greater risk of overheating in warm environments.
- The blood supply to the dermis is reduced. Reduction in blood flow causes the skin to cool, which in turn can stimulate thermoreceptors, making a person feel cold even in a warm room. However, reduced circulation and sweat gland function in older people lessens their ability to lose

body heat. For this reason, overexertion or exposure to high temperatures (such as those in a sauna or hot tub) can cause body temperatures to soar dangerously high.

- Hair follicles stop functioning or produce thinner, finer hairs. With decreased melanocyte activity, these hairs become gray or white.
- The dermis thins, and the elastic fiber network decreases in size. As a result, the integument becomes weaker and less resilient, and sagging and wrinkling occur. These effects are most noticeable in body areas that have been exposed to the sun.
- With changes in levels of sex hormones, secondary sexual characteristics in hair and body fat distribution begin to fade.
- Skin repair is slower. Repairs to an uninfected blister might take 3 to 4 weeks in a young adult, but the same repairs could take 6 to 8 weeks at age 65–75. Because healing takes place more slowly, recurring infections may result.

Build Your Knowledge **Figure 5-18** reviews the integumentary system. Build Your Knowledge figures will appear after each body system has been covered and are intended to help build your understanding of the interconnections among all other body systems. Since we have covered only one body system thus far, **Figure 5-18** does not include references to body systems covered in upcoming chapters.

Checkpoint

31. Older people do not tolerate the summer heat as well as they did when they were young, and they are more prone to heat-related illnesses. What accounts for these changes?
32. Why does hair turn white or gray with age?

See the blue Answers tab at the back of the book.

Build Your Knowledge

Figure 5–18 Integration of the INTEGUMENTARY system with the other body systems presented so far.

Integumentary System

The Integumentary System performs a variety of functions for the human body. It:

- covers and protects underlying tissues and organs from impacts, abrasions, chemicals, and infections, and it prevents the loss of body fluids
- maintains normal body temperature by regulating heat exchange with the environment
- synthesizes vitamin D₃ in the epidermis, which aids calcium uptake and stores large reserves of lipids in the dermis
- detects touch, pressure, pain, and temperature stimuli
- excretes salts, water, and organic wastes
- coordinates the immune response to pathogens and skin cancers

About the Build Your Knowledge Figures

Since each body system interacts with all the others, no one system can be completely understood in isolation. The integration of the various systems allows the human body to function seamlessly, and when disease or injury strikes, multiple systems must respond for healing to occur. Homeostasis depends on the thorough integration of all the body systems working as one.

These figures will introduce the body systems one by one and show how each influences the others to make them function more effectively. As we progress through the systems, you will *build your knowledge* about the complementary nature of the interactions between the various body systems.

5 Chapter Review

Study Outline

An Introduction to the Integumentary System

1. The **integument**, or **integumentary system**, consists of the **cutaneous membrane**, or **skin** (which includes the **epidermis** and the **dermis**) and the **accessory structures**. Beneath the dermis lies the **subcutaneous layer** (*hypodermis*). (Figures 5-1, 5-2)
2. Functions of the integument include *protection, excretion, temperature maintenance, vitamin D₃ synthesis, nutrient storage, sensory detection, and coordination of the immune response.* (Figure 5-2)

5-1 The epidermis is a protective covering composed of layers with various functions

3. **Thin skin**, consisting of four layers of **keratinocytes**, covers most of the body. Heavily abraded body surfaces may be covered by **thick skin** containing five layers of keratinocytes. (Spotlight Figure 5-3)
4. The epidermis provides physical protection, prevents fluid loss, and helps keep microorganisms out of the body.
5. Cell divisions in the **stratum basale**, the deepest epidermal layer, replace more superficial cells. (Spotlight Figure 5-3)
6. As epidermal cells age, they pass through the **stratum basale**, the **stratum spinosum**, the **stratum granulosum**, the **stratum lucidum** (in thick skin), and the **stratum corneum**. In the process, they accumulate large amounts of **keratin**. Ultimately, the cells are shed. (Spotlight Figure 5-3)
7. The epidermis and dermis are bonded together by **epidermal ridges** interlocked with **dermal papillae**. (Spotlight Figure 5-3)
8. *Dendritic (Langerhans) cells* in the stratum spinosum are part of the immune system. *Tactile (Merkel) cells* in the stratum basale provide sensory information about objects that touch the skin.
9. **Epidermal growth factor (EGF)** promotes growth, division, and repair of the epidermis and epithelial gland synthesis and secretion of secretory product.

5-2 The dermis is the tissue layer that supports the epidermis

10. The dermis consists of the superficial **papillary layer** and the deeper **reticular layer**. (Figures 5-1, 5-2, 5-4)
11. The papillary layer of the dermis contains blood vessels, lymphatic vessels, and sensory nerves that supply the epidermis. The reticular layer consists of a meshwork of collagen and elastic fibers oriented to resist tension in the skin.
12. Extensive distention of the dermis can cause **stretch marks**.
13. The pattern of collagen and elastic fiber bundles forms **tension lines** (cleavage lines). (Figure 5-5)
14. Arteries to the skin form the **cutaneous plexus** in the subcutaneous layer. The **subpapillary plexus** is at the base of the papillary layer of the dermis. (Figure 5-6)
15. Integumentary sensory receptors detect both light touch and pressure.

Media Resources:

- Chapter Quizzes, Chapter Practice Test, MP3 Tutor Sessions, and Clinical Case Studies
- Practice Anatomy Lab
- Interactive Physiology
- A&P Flix
- PhysioEx

5-3 The subcutaneous layer connects the dermis to underlying tissues

16. The **subcutaneous layer** (*hypodermis*) stabilizes the skin's position against underlying organs and tissues. (Figures 5-1, 5-7)

5-4 Epidermal pigmentation and dermal circulation influence skin color

17. The color of the epidermis depends on two factors: epidermal pigmentation and dermal blood supply.
18. The epidermis contains the pigments **melanin** and **carotene**. **Melanocytes**, which produce melanin, protect us from **ultra-violet (UV) radiation**. (Figure 5-8)
19. Interruptions of the dermal blood supply or poor oxygenation in the lungs can lead to **cyanosis**. **Vitiligo** is the appearance of nonpigmented white patches of various sizes on otherwise normally pigmented skin. (Figure 5-9)

5-5 Sunlight causes epidermal cells to convert a steroid into vitamin D₃

20. Epidermal cells synthesize **vitamin D₃**, or **cholecalciferol**, when exposed to the UV radiation in sunlight. **Rickets** is a disease caused by vitamin D₃ deficiency. (Figures 5-10, 5-11)

5-6 Hair is made of keratinized dead cells pushed to the skin surface, where it has protecting and insulating roles

21. **Hairs** originate in complex organs called **hair follicles**. Each hair has a **root** and a **shaft**. At the base of the root are a **hair papilla**, surrounded by a **hair bulb**, and a **root hair plexus** of sensory nerves. Hairs have a **medulla**, or core of soft keratin, surrounded by a **cortex** of hard keratin. The **cuticle** is a superficial layer of dead cells that protects the hair. (Figure 5-12)
22. Our bodies have both **vellus hairs** ("peach fuzz") and heavy **terminal hairs**. A hair that has stopped growing is called a **club hair**. A curly hair and its follicle are oval; a straight hair and its follicle are round.
23. Each **arrector pili muscle** (*arrector muscle of hair*) can erect a single hair. (Figure 5-12)
24. Our hairs grow and are shed according to the **hair growth cycle**. A typical hair on the head grows for 2 to 5 years and is then shed.

5-7 Sebaceous glands and sweat glands are exocrine glands found in the skin

25. A typical **sebaceous gland** discharges waxy **sebum** into a lumen and, ultimately, into a hair follicle. **Sebaceous follicles** are large sebaceous glands that discharge sebum directly onto the epidermis. (Figure 5-13)

26. The two types of **sweat glands**, or *sudoriferous glands*, are apocrine and eccrine (*merocrine*) sweat glands. **Apocrine sweat glands** produce an odorous secretion. The more numerous **eccrine sweat glands** produce a watery secretion known as sensible perspiration. (Figure 5–14)
27. **Mammary glands** of the breasts are structurally similar to apocrine sweat glands. **Ceruminous glands** in the ear produce a waxy substance called **cerumen**.

5-8 Nails are keratinized epidermal cells that protect the tips of fingers and toes

28. The **nail body** of a **nail** covers the **nail bed**. Nail production occurs at the **nail root**, which is covered by the **cuticle**, or **eponychium**. The **free edge** of the nail extends over the **hyponychium**. (Figure 5–15)

5-9 After an injury, the integument is repaired in several phases

29. Based on the division of stem cells, the skin can regenerate effectively even after considerable damage. The process begins with bleeding and inflammation (*inflammation phase*), the formation of a **scab** and **granulation tissue** (*migration phase*), loss of granulation tissue and undermining of the scab (*proliferation phase*), and ends with the creation of **scar tissue** (*scarring phase*). (Figure 5–16)
30. **Keloids** are raised areas of fibrous scar tissue. (Figure 5–17)

5-10 Effects of aging on the skin include thinning, wrinkling, and reduced melanocyte activity

31. With aging, the integument thins, blood flow decreases, cellular activity decreases, and repairs take place more slowly.
32. The integumentary system provides physical protection for all other body systems. (Figure 5–18)

Review Questions

See the blue Answers tab at the back of the book.

LEVEL 1 Reviewing Facts and Terms

- Identify the different portions (**a–d**) of the cutaneous membrane and the underlying layer of loose connective tissue (**e**) in the diagram to the right.
 - _____
 - _____
 - _____
 - _____
 - _____
- The two major components of the integumentary system are (**a**) the cutaneous membrane and the accessory structures, (**b**) the epidermis and the subcutaneous layer, (**c**) the hair and the nails, (**d**) the dermis and the subcutaneous layer.
- Beginning at the basement membrane and traveling toward the free surface, the epidermis includes the following strata: (**a**) corneum, lucidum, granulosum, spinosum, basale, (**b**) granulosum, lucidum, spinosum, basale, corneum, (**c**) basale, spinosum, granulosum, lucidum, corneum, (**d**) lucidum, granulosum, spinosum, basale, corneum.
- A glassy layer present only in thick skin is the (**a**) stratum corneum, (**b**) stratum lucidum, (**c**) stratum granulosum, (**d**) stratum spinosum, (**e**) stratum basale.
- Exposure of the skin to ultraviolet (UV) radiation (**a**) can result in increased numbers of melanocytes forming in the skin, (**b**) can result in decreased melanin production in melanocytes, (**c**) can cause destruction of vitamin D₃, (**d**) can result in damage to the DNA of cells in the stratum basale, (**e**) has no effect on the skin cells.
- Which layer of the dermis is involved in dermatitis? (**a**) the subcutaneous layer, (**b**) the superficial fascia, (**c**) the reticular layer, (**d**) the papillary layer.
- The lamellar corpuscles in the reticular layer of the dermis are specialized in sensing (**a**) pain, (**b**) deep pressure and vibration, (**c**) temperature, (**d**) a light touch.

- What is impetigo? (**a**) an idiopathic autoimmune disease, (**b**) a skin infection caused by streptococcus and staphylococcus bacteria, (**c**) a skin infection involving an entire hair follicle, (**d**) a benign pigmented spot on the skin.
- Each of the following is a part of the hair follicle, *except* the (**a**) glassy membrane, (**b**) external root sheath, (**c**) internal root sheath, (**d**) eponychium.
- Ceruminous glands are found (**a**) in the passageway of the external ear, (**b**) in the breasts, (**c**) near hair follicles, (**d**) in the armpits.
- Sebaceous follicles are large sebaceous glands found on all the following body parts *except* the (**a**) face, (**b**) external genitalia, (**c**) arms, (**d**) nipples.
- An important example of a specialized gland in the skin is the (**a**) mammary gland, (**b**) mucous gland, (**c**) apocrine sweat gland, (**d**) eccrine sweat gland.
- The cells that create scar tissue during the repair of an injury are (**a**) mast cells, (**b**) macrophages, (**c**) fibroblasts, (**d**) melanocytes.
- What would a person whose skin and whites of the eye are yellow be suffering from? (**a**) vitiligo, (**b**) overproduction of MSH, (**c**) jaundice, (**d**) a vitamin D deficiency.
- In which layer(s) of the epidermis does cell division occur?
- Which skin receptors are sensitive to a light touch?
- What widespread effects does epidermal growth factor (EGF) have on the integument?
- What two major layers constitute the dermis, and what components are in each layer?
- List three skin functions that are affected by burns on more than 20 percent of the body's surface.

LEVEL 2 Reviewing Concepts

- How is thin skin different from thick skin?
- In clinical practice, drugs can be delivered by diffusion across the skin. This delivery method is called *transdermal administration*. Why are fat-soluble drugs more suitable for transdermal administration than drugs that are water-soluble?
- In evaluating burns, it is important to determine the depth of the burn correctly. How would you differentiate among a first-degree burn, a second-degree burn, and a third-degree burn?

23. Why is it important for a surgeon to choose—when possible—an incision pattern according to the skin's tension lines?
 24. The fibrous protein that is responsible for the strength and water resistance of the skin surface is **(a)** collagen, **(b)** eleidin, **(c)** keratin, **(d)** elastin, **(e)** keratohyalin.
 25. The darker a person's skin color, **(a)** the more melanocytes are in the skin, **(b)** the more layers are in the epidermis, **(c)** the more melanin the melanocytes produce, **(d)** the more superficial the blood vessels.
 26. For bacteria on the skin to cause an infection in the skin, they must accomplish all the following, *except* **(a)** survive the bactericidal components of sebum, **(b)** avoid being flushed from the surface of the skin by sweat, **(c)** penetrate the stratum corneum, **(d)** penetrate to the level of the capillaries, **(e)** escape the dendritic cells.
- LEVEL 3 Critical Thinking and Clinical Applications**
27. In older persons, blood supply to the dermis is reduced and sweat glands are less active. This combination of factors would most affect **(a)** the ability to thermoregulate, **(b)** the ability to heal injured skin, **(c)** the ease with which the skin is injured, **(d)** the physical characteristics of the skin, **(e)** the ability to grow hair.
 28. Lisa is unhappy about the presence of white patches on several parts of her body. These patches do not cause pain or discomfort, but Lisa considers them disfiguring. Identify Lisa's condition, and explain what has caused it.
 29. Exposure to optimum amounts of sunlight is necessary for proper bone maintenance and growth in children. **(a)** What does sunlight do to promote bone maintenance and growth? **(b)** If a child lives in an area where exposure to sunlight is limited because of pollution or overcast skies, what can be done to minimize impaired maintenance and growth of bone?
 30. One of the factors to which lie detectors respond is an increase in electrical skin conductance due to the presence of moisture. Explain the physiological basis for the use of this indicator.
 31. A patient is brought to the hospital with severe burns. The burned skin looks seriously damaged. The pain, however, is bearable. Careful examination shows that the damage extended into the subcutaneous layer. How would you evaluate this type of burn? Will it heal by itself?

CLINICAL CASE Wrap-Up He Has Fish Skin!

Grandpa Will has *ichthyosis vulgaris* (IK-thē-oh-sis vōl-GĀR-is). Ichthyosis literally means “fish-like condition,” a feature his grandsons noticed right away. Will inherited this skin condition from his parents, who carried a gene mutation for a structural protein. The lack of this protein impairs keratinization. With this condition, skin cells also have fewer desmosomes and tight junctions, so the epidermis becomes dry and flaky, resembling fish scales.

There is no cure. Every day Grandpa Will must tend to his skin by applying moisturizers to draw and retain moisture and emollients to soften the scales.

He avoids soap that further dries his skin and uses rubber gloves to wash the dishes. In winter, he runs a humidifier in the bedroom. Grandpa Will must be diligent about caring for his skin because it can break into deep, painful cracks, creating an environment for secondary infections.

1. Why is ichthyosis called a “disorder of cornification”? Which cells are involved?
2. Grandpa Will has trouble when it's hot outside. What's wrong?

See the blue Answers tab at the back of the book.

Related Clinical Terms

carbuncle: A skin infection that often involves a group of hair follicles. The infected material forms a lump, which occurs deep in the skin; the medical term for multiple boils.

cold sore: A lesion that typically occurs in or around the mouth and is caused by a dormant herpes simplex virus that may be reactivated by factors such as stress, fever, or sunburn. Also called *fever blister*.

comedo: The primary sign of acne consisting of an enlarged pore filled with skin debris, bacteria, and sebum (oil); the medical term for a blackhead.

dermatology: The branch of medicine concerned with the diagnosis, treatment, and prevention of diseases of the skin, hair, and nails.

eczema: Rash characterized by inflamed, itchy, dry, scaly, or irritated skin.

frostbite: Injury to body tissues caused by exposure to below-freezing temperatures, typically affecting the nose, fingers, or toes and sometimes resulting in gangrene.

furuncle: A skin infection involving an entire hair follicle and nearby skin tissue; the medical term for a boil.

gangrene: A term that describes dead or dying body tissue that occurs because the local blood supply to the tissue is either lost or is inadequate to keep the tissue alive.

impetigo: An infection of the surface of the skin, caused by staphylococcus (“staph”) and streptococcus (“strep”) bacteria.

nevus: A benign pigmented spot on the skin such as a mole.

onycholysis: A nail disorder characterized by a spontaneous separation of the nail bed starting at the distal free margin and progressing proximally.

pallor: An unhealthy pale appearance.

porphyria: A rare hereditary disease in which the blood pigment hemoglobin is abnormally metabolized. Porphyrins are excreted in the urine, which becomes dark; other symptoms include mental disturbances and extreme sensitivity of the skin to light.

rosacea: A condition in which certain facial blood vessels enlarge, giving the cheeks and nose a flushed appearance.

scleroderma: An idiopathic chronic autoimmune disease characterized by hardening and contraction of the skin and connective tissue, either locally or throughout the body.

tinea: A skin infection caused by a fungus; also called *ringworm*.

urticaria: Skin condition characterized by red, itchy, raised areas that appear in varying shapes and sizes; commonly called *hives*.

6

Bones and Bone Structure

Learning Outcomes

These Learning Outcomes correspond by number to this chapter's sections and indicate what you should be able to do after completing the chapter.

- 6-1 ■ Describe the major functions of the skeletal system.
- 6-2 ■ Classify bones according to shape and structure, giving examples of each type, and explain the functional significance of each of the major types of bone markings.
- 6-3 ■ Identify the cell types in bone and list their major functions.
- 6-4 ■ Compare the structures and functions of compact bone and spongy bone.
- 6-5 ■ Compare the mechanisms of endochondral ossification and intramembranous ossification.
- 6-6 ■ Describe the remodeling and homeostatic mechanisms of the skeletal system.
- 6-7 ■ Discuss the effects of exercise, nutrition, and hormones on bone development and on the skeletal system.
- 6-8 ■ Explain the role of calcium as it relates to the skeletal system.
- 6-9 ■ Describe the types of fractures and explain how fractures heal.
- 6-10 ■ Summarize the effects of the aging process on the skeletal system.

CLINICAL CASE

A Case of Child Abuse?

Alex's mom has been waiting in the emergency room for over 2 hours since her son was wheeled off to get an x-ray. Alex had been carried home from third-grade soccer practice. The coach said she had not witnessed the injury, but it seemed like Alex had twisted and fallen without even having contact with another player. He was unable to put weight on his left leg.

A young man, *not* wearing a white coat, approaches her. “Mrs. Otero, I am Mr. Wang, the hospital social worker. I am here to speak with you about your son, Alex. Alex has an acute fracture of his tibia and fibula—the bones in his leg—but he also has two healed rib fractures and a healing fracture of his upper arm as well. We fear he has been the victim

of child abuse, so he is being admitted until we can investigate further.”

Mrs. Otero is dumbfounded by the suggestion of child abuse. She knows that no one at home has hurt him. Alex had complained about shoulder pain after playing on the monkey bars a few weeks ago, but she had not suspected his arm was broken. She considered Alex to be a lot like her. Both were somewhat fragile and prone to breaking bones, although she had not had any more fractures since adulthood. They both had soft, discolored teeth. And, oddly enough, the whites of

their eyes had a blue tint. **If Alex is not a victim of child abuse, what else could explain his multiple fractures? To find out, turn to the Clinical Case Wrap-Up at the end of the chapter.**

6

An Introduction to Bones and Bone Tissue

Many people might think of the skeleton as being rather boring, but this is far from the truth. The bones of the skeleton are more than just racks from which muscles hang; they have a variety of vital functions. Our bones are complex, dynamic organs that constantly change to adapt to the demands we place on them. In addition to other functions, bones support the weight of the body and work with muscles to maintain body position and to produce controlled, precise movements. Without the skeleton to pull against, contracting muscle fibers could not make us sit, stand, walk, or run.

Chapters 6–9 describe the structure and function of the skeletal system. This chapter starts with a brief introduction to the skeletal system and then expands on the introduction to bone presented in Chapter 4 by describing bone, or osseous tissue, a supporting connective tissue. We also examine the mechanisms involved in the growth, remodeling, and repair of the skeleton. Throughout the chapter we explore how the structure of bones allows them to perform their many functions.

6-1 The skeletal system has several major functions

Learning Outcome Describe the major functions of the skeletal system.

The **skeletal system** includes the bones of the skeleton and the cartilages, ligaments, and other connective tissues that stabilize or interconnect the bones. This system has the following major functions:

- **Support.** The skeletal system provides structural support for the entire body. Individual bones or groups of bones provide a framework for the attachment of soft tissues and organs.
- **Storage of Minerals and Lipids.** Minerals are inorganic ions that contribute to the osmotic concentration of body fluids. They also take part in various physiological processes, and several are important as enzyme cofactors. Calcium is the most abundant mineral in the human body. The calcium salts of bone are a valuable mineral reserve that maintains normal concentrations of calcium and phosphate ions in body fluids. In addition, the bones of the skeleton store energy in the form of lipids in *yellow bone marrow*, an adipose tissue that is found in certain internal bone cavities.
- **Blood Cell Production.** Red blood cells, white blood cells, and other blood elements are produced in *red bone marrow*, which fills the internal cavities of many bones. We describe blood cell formation when we examine the cardiovascular and lymphatic systems in later chapters.
- **Protection.** Skeletal structures surround many soft tissues and organs. The ribs protect the heart and lungs, the skull encloses the brain, the vertebrae shield the spinal cord, and the pelvis cradles digestive and reproductive organs.
- **Leverage.** Many bones function as levers that can change the magnitude and direction of the forces generated by skeletal muscles. The movements produced range from the precise motion of a fingertip to changes in the position of the entire body.

The features and properties of the skeletal system ultimately depend on the unique and dynamic properties of bone. The bone specimens in lab or the skeletons of dead animals are

only the dry remains of this living tissue. They have the same relationship to the bone in a living organism as a kiln-dried two-by-four board has to a living oak tree.

✓ Checkpoint

1. Name the major functions of the skeletal system.

See the blue Answers tab at the back of the book.

6-2 Bones are classified according to shape and structure, and they have a variety of bone markings

- 6 **Learning Outcome** Classify bones according to shape and structure, giving examples of each type, and explain the functional significance of each of the major types of bone markings.

Bones are categorized by their general shape and structure. We begin our discussion with bone shapes, turn our attention to the bumps, grooves, and openings associated with bones, and then close with bone structure.

Bone Shapes

The adult skeleton typically contains 206 major bones. We can divide these into the following six broad categories according to their individual shapes (**Figure 6-1**):

- **Sutural bones**, or *Wormian bones*, are small, flat, irregularly shaped bones between the flat bones of the skull (**Figure 6-1a**). There are individual variations in the number, shape, and position of the sutural bones.
- **Irregular bones** have complex shapes (**Figure 6-1b**).

Figure 6-1 A Classification of Bones by Shape.

- **Short bones** are boxy, with approximately equal dimensions (**Figure 6-1c**).
- **Flat bones** have thin, parallel surfaces, which produce a flattened shape (**Figure 6-1d**).
- **Long bones** are relatively long and slender, consisting of a shaft with two ends that are wider than the shaft (**Figure 6-1e**).
- **Sesamoid bones** are usually small, round, and flat, and shaped somewhat like a sesame seed (**Figure 6-1f**). They tend to develop within tendons. Except for each patella (pa-TEL-uh; *patella*, shallow dish), or kneecap, there are individual variations in the location and number of sesamoid bones, which can form in numerous areas. These variations, along with varying numbers of sutural bones, account for individual differences in the total number of bones in the skeleton.

Bone Markings

The surfaces of each bone have characteristic **bone markings** or *surface features*. Examples include projections, openings, and depressions. Projections form where muscles, tendons, and ligaments attach and where adjacent bones form joints. Openings and depressions in bone are sites where blood vessels or nerves lie alongside or penetrate the bone. Detailed examination of bone markings can yield an abundance of anatomical information. For example, anthropologists, criminologists, and pathologists can often determine the size, age, sex, and general appearance of an individual based on incomplete skeletal remains.

Figure 6-2 introduces the prominent bone markings. It illustrates specific anatomical terms for the various projections, depressions, and openings. These bone markings provide fixed landmarks that can help us determine the position of the soft-tissue components of other organ systems.

Bone Structure

Figure 6-3a introduces the anatomy of the femur, the long bone of the thigh. This representative long bone has an extended tubular shaft, or **diaphysis** (dī-AF-i-sis). At each end is an expanded area known as the **epiphysis** (ē-PIF-i-sis). The diaphysis is connected to each epiphysis at a narrow zone known as the **metaphysis** (me-TAF-i-sis; *meta*, between).

The wall of the diaphysis consists of a layer of compact bone. **Compact bone** is relatively dense and solid. Compact bone forms a sturdy protective layer that surrounds a central space called the **medullary cavity** (*medulla*, innermost part), or *marrow cavity*.

The epiphyses consist largely of spongy bone. **Spongy bone**, also called *trabecular* (tra-BEK-yū-lar) *bone*, consists of an open network of struts and plates that resembles a three-dimensional garden latticework.

Figure 6-3b shows the structure of a flat bone from the skull, one of the *parietal* (pa-RĪ-e-tul) *bones*. A flat bone resembles a spongy bone sandwich, with layers of compact bone covering a core of spongy bone. Within the cranium, the layer of spongy bone between the layers of compact bone is called the *diploë* (DIP-lō-ē; *diplous*, twofold). Red bone marrow is present within spongy bone, but there is no large medullary cavity as in the diaphysis of a long bone.

Next, we consider the histology of a typical bone.

✓ Checkpoint

2. Identify the categories used for classifying a bone according to shape.
3. Define bone markings.

See the blue Answers tab at the back of the book.

6-3 Bone is composed of matrix and several types of cells: osteogenic cells, osteoblasts, osteocytes, and osteoclasts

Learning Outcome Identify the cell types in bone and list their major functions.

Bone tissue is a supporting connective tissue. Like other connective tissues, it contains specialized cells and a matrix consisting of extracellular protein fibers and a ground substance. (You may want to review the sections on dense connective tissues, cartilage, and bone in Chapter 4 now.)

Recall these characteristics of bone:

- The matrix of bone is very dense due to deposits of calcium salts around the protein fibers.
- The matrix contains bone cells, or *osteocytes* (OS-tē-ō-sītz), within pockets called *lacunae* (la-KŪ-nē). (The same term is used for the spaces that chondrocytes occupy in cartilage.) The lacunae of bone are typically organized around blood vessels that branch through the bony matrix.
- *Canaliculi* (kan-a-LIK-yū-lī), narrow passageways through the matrix, extend between the lacunae and nearby blood vessels, forming a branching network through which osteocytes exchange nutrients, wastes, and gases.
- Except at joints, a *periosteum* (per-ē-OS-tē-um) covers the outer surfaces of bones. It consists of an outer fibrous layer and an inner cellular layer.

We now take a closer look at the organization of the matrix and cells of bone.

Bone Matrix

Calcium phosphate, $\text{Ca}_3(\text{PO}_4)_2$, makes up almost two-thirds of bone weight. Calcium phosphate interacts with calcium

Figure 6–2 An Introduction to Bone Markings.

Figure 6–3 Bone Structure.**a** The structure of a representative long bone (the femur) in longitudinal section**b** The structure of a flat bone (the parietal bone)

Where is spongy bone found in long bones? Where is spongy bone found in flat bones?

Figure 6–4 Bone Without a Calcified Matrix.

When subjected to tension (pull), they are stronger than steel. They are flexible as well as tough and can easily tolerate twisting and bending but offer little resistance to compression. When compressed, they simply bend out of the way.

The composition of the matrix in compact bone is the same as that in spongy bone. The collagen fibers provide an organic framework for the formation of hydroxyapatite crystals. These crystals form small plates and rods that are locked into the collagen fibers at regular angles. The result is a protein-crystal combination that has the flexibility of collagen and the compressive strength of hydroxyapatite crystals. The protein-crystal interactions allow bone to be strong, somewhat flexible, and highly resistant to breaking or shattering under compression.

In its overall properties, bone is on par with the best steel-reinforced concrete. In fact, bone is far superior to concrete, because it can undergo remodeling (cycles of bone formation and resorption) as needed and can repair itself after injury.

Bone Cells

Bone contains four types of cells: osteogenic cells, osteoblasts, osteocytes, and osteoclasts (**Figure 6–5**).

Osteogenic Cells

Bone contains small numbers of mesenchymal cells called **osteogenic** (os-tē-ō-JEN-ik) **cells**, or **osteoprogenitor** (os-tē-ō-prō-JEN-i-tor) **cells**. These stem cells divide to produce daughter cells that differentiate into osteoblasts (**Figure 6–5a**). Osteogenic cells maintain populations of osteoblasts and so are important in the repair of a *fracture* (a break or a crack in a bone). Osteogenic cells are found in the inner, cellular layer of the periosteum. They are also found in a cellular layer, or *endosteum*, that lines medullary cavities and passageways for blood vessels that penetrate the matrix of compact bone.

Figure 6–5 Types of Bone Cells.

Which three types of bone cells are developmentally related and what is their progression from the earliest to the latest stage?

Osteoblasts

Osteoblasts (OS-tē-ō-blasts; *-blast*, immature precursor cell) produce new bone matrix in a process called **osteogenesis** (os-tē-ō-JEN-e-sis; *genesis*, production) or **ossification** (os-i-fi-KĀ-shun). Osteoblasts make and release the proteins and other organic components of the matrix. Before calcium salts are deposited, this organic matrix is called **osteoid** (OS-tē-oyd) (**Figure 6–5b**). Osteoblasts also help increase local concentrations of calcium phosphate above its solubility threshold, triggering the deposition of calcium salts in the organic matrix. This process converts osteoid to bone. Osteocytes develop from osteoblasts that have become completely surrounded by bone matrix.

Osteocytes

Osteocytes (*osteo-*, bone + *-cyte*, cell) are mature bone cells that make up most of the cell population. Each osteocyte occupies a lacuna, a pocket sandwiched between layers of matrix (**Figure 6–5c**). Osteocytes cannot divide, and a lacuna never contains more than one osteocyte.

Narrow passageways called **canaliculi** radiate through the matrix. Canaliculi contain cytoplasmic extensions of osteocytes, thus supporting cell-to-cell communication between osteocytes in different lacunae and access to nutrients supplied

by blood vessels in the central canal. Neighboring osteocytes are linked by gap junctions, which permit the cells to rapidly exchange ions and small molecules, including nutrients and hormones. The interstitial fluid that surrounds the osteocytes and their extensions is an additional route for the diffusion of nutrients and wastes.

Osteocytes have two major functions:

1. *Osteocytes maintain the protein and mineral content of the surrounding matrix.* Matrix components are continually turned over (recycled). Osteocytes secrete chemicals that dissolve the adjacent matrix, and the minerals released enter the circulation. Osteocytes then rebuild the matrix, stimulating the deposition of new hydroxyapatite crystals. The turnover rate varies from bone to bone. We consider this process further in a later section.
2. *Osteocytes take part in the repair of damaged bone.* If released from their lacunae, osteocytes can convert to a less specialized type of cell, such as an osteoblast or an osteogenic cell. These additional cells assist bone repair.

Osteoclasts

Osteoclasts (OS-tē-ō-clasts; *klastos*, broken) are cells that absorb and remove bone matrix (**Figure 6–5d**). They are large multinucleate cells with 50 or more nuclei. The osteoclasts

generally occur in shallow depressions called *osteoclastic crypts* (*Howship's lacunae*) that they have eroded into the matrix. Osteoclasts secrete acids and protein-digesting enzymes that dissolve the matrix and release the stored minerals. During this process, fingerlike processes, called the *ruffled border*, increase the secretory surface area of the cell in contact with the surrounding matrix. This erosion process is called **osteolysis** (os-tē-OL-i-sis; *osteo-*, bone + *lysis*, a loosening), or *resorption*. The released products are resorbed at this border. Osteolysis is an important part of the regulation of calcium and phosphate ion concentrations in body fluids.

Osteoclasts are not related to osteogenic cells or their descendants. Instead, they are derived from the same stem cells that produce monocytes and macrophages, which are cells involved in the body's defense mechanisms.

We look at how these bone cells function together in Section 6-6.

✓ Checkpoint

4. Mature bone cells are known as _____, bone-building cells are called _____, and _____ are bone-resorbing cells.
5. How would the compressive strength of a bone be affected if its ratio of collagen to hydroxyapatite increased?
6. If the activity of osteoclasts exceeds the activity of osteoblasts in a bone, how will the mass of the bone be affected?

See the blue Answers tab at the back of the book.

6-4 Compact bone contains parallel osteons, and spongy bone contains trabeculae

Learning Outcome Compare the structures and functions of compact bone and spongy bone.

Compact bone functions to protect, support, and resist stress. Spongy bone provides some support and stores marrow. In this section, we examine in detail the structures of compact and spongy bone, which allow these types of bone to perform their functions. We also look at the outer covering and inner lining of bone, called the periosteum and endosteum, respectively.

Compact Bone Structure

At the microscopic level, the basic functional unit of mature compact bone is the **osteon** (OS-tē-on), or *Haversian* (ha-VER-jhun) *system*. In an osteon, the osteocytes are arranged in concentric layers around a vascular **central canal**, or *Haversian canal* (**Figure 6-6**). This canal contains one or more blood vessels (normally a capillary and a *venule*, a very small vein) that carry blood to and from the osteon (**Figure 6-7a**).

Figure 6-6 Osteons of Compact Bone.

Central canals generally run parallel to the surface of the bone. Other passageways, known as **perforating canals**, or *Volkman's* (FÖLK-manz) *canals*, extend perpendicular to the surface. Blood vessels in these canals supply blood both to osteons deeper in the bone and to tissues of the medullary cavity.

Bone matrix forms layers called **lamellae** (lah-MEL-lē; singular, *lamella*, a thin plate). The lamellae of each osteon form a series of nested cylinders around the central canal. In transverse section, these *concentric lamellae* create a target-like pattern, with the central canal as the bull's-eye. Collagen fibers within each lamella form a spiral pattern that adds strength and resiliency (**Figure 6-7b**).

Interstitial lamellae fill in the spaces between the osteons in compact bone. These lamellae are remnants of osteons whose matrix components have been almost completely recycled by osteoclasts. *Circumferential lamellae* (*circum-*, around + *ferre*, to bear) are found at the outer and inner surfaces of the bone, where they are covered by the periosteum and endosteum, respectively (**Figure 6-7**). These lamellae are produced during the growth of the bone, as we describe in Section 6-6.

Tips

To understand the relationship of collagen fibers to bone matrix, think about the reinforcing steel rods (rebar) in concrete. Like the rebar in concrete, collagen adds tensional strength and flexibility to bone.

Compact bone is thickest where stresses are applied from a limited number of directions. All osteons in compact bone are aligned the same, making such bones very strong when stressed along the axis of alignment. Think of a single osteon as a drinking straw with very thick walls. When pushing the ends of the straw together or pulling them apart, the straw is

Figure 6–7 The Structure of Compact Bone.

What are the three ways in which lamellae are organized in compact bone?

quite strong. But when holding the ends and pushing from the side, the straw will easily bend at a sharp angle.

The osteons in the diaphysis of a long bone are parallel to the long axis of the shaft. For this reason, the shaft does not bend, even when extreme forces are applied to either end. (The femur can withstand 10–15 times the body's weight without breaking.) Yet a much smaller force applied to the side of the shaft can break the femur. A sudden sideways force, as in a fall or auto accident, causes most breaks in this bone.

Spongy Bone Structure

In spongy bone, lamellae are not arranged in osteons. No osteons are present. The matrix in spongy bone forms a meshwork of supporting bundles of fibers called **trabeculae** (tra-BEK-ū-lē) (Figure 6–8). These thin trabeculae branch,

creating an open network. The trabeculae are oriented along stress lines and extensively cross-braced.

Spongy bone is found where bones are not heavily stressed or where stresses originate from many directions. In addition, spongy bone is less dense than compact bone. Spongy bone reduces the weight of the skeleton, making it easier for muscles to move the bones.

There are no capillaries or venules in the matrix of spongy bone. Instead, spongy bone within the epiphyses of long bones, such as the femur, and the interior of other large bones such as the sternum and ilium (a large bone of the pelvis) contains **red bone marrow**, which forms blood cells. The framework of trabeculae supports and protects the cells of the bone marrow. Blood vessels within this tissue deliver nutrients to the osteocytes by diffusion along canaliculi that open onto the surfaces

Figure 6–8 The Structure of Spongy Bone.

of trabeculae; they also remove wastes generated by the osteocytes. At other sites, spongy bone may contain **yellow bone marrow**—adipose tissue important as an energy reserve.

Coordinated Functions of Compact and Spongy Bone

How do compact bone and spongy bone work together to support the body's weight? **Figure 6–9** shows the distribution of forces applied to the femur at the hip joint and illustrates the functional relationship between compact bone and spongy bone. The head of the femur articulates with a socket on the lateral surface of the pelvis. At the proximal epiphysis of the femur, trabeculae transfer forces from the pelvis to the compact bone of the femoral shaft, across the hip joint. At the distal epiphysis, trabeculae transfer weight from the shaft to the leg, across the knee joint. The femoral head projects medially, and the body weight compresses the medial side of the shaft. However, because the force is applied off center, the bone must also resist the tendency to bend into a lateral bow. The resistance to such bending arises through the stretching load, or *tension*, that develops in the lateral portion of the shaft as its medial portion is under compression. The medullary cavity does not reduce the bone's strength because the center of the bone is not subjected to compression or tension.

Surface Coverings of Bone

Bones have two types of coverings: periosteum on the outside and endosteum lining the inside. Let's look in more detail at each of these coverings.

Figure 6–9 The Distribution of Forces on a Long Bone.

The femur, or thigh bone, has a diaphysis (shaft) with walls of compact bone and epiphyses filled with spongy bone. The body weight is transferred to the femur at the hip joint. Because the hip joint is off-center relative to the axis of the shaft, the body weight is distributed along the bone in a way that compresses the medial (inner) portion of the shaft and stretches the lateral (outer) portion.

The Periosteum

Except within joint cavities, the superficial layer of compact bone that covers all bones is wrapped by a **periosteum** (*peri*, around), a membrane with a fibrous outer layer and a cellular inner layer (**Figure 6–10a**). The periosteum (1) isolates the bone from surrounding tissues, (2) provides a route for the blood vessels and nerves, and (3) takes part in bone growth and repair.

Near joints, the periosteum becomes continuous with the connective tissues that hold the bones in place. At a joint that permits significant amounts of movement, called a *synovial* (si-NŌ-vē-ul) *joint*, the periosteum is continuous with the joint capsule. The fibers of the periosteum are also interwoven with those of the tendons attached to the bone. As the bone grows, these tendon fibers are cemented into the circumferential lamellae by osteoblasts from the cellular layer of the periosteum. Collagen fibers incorporated into bone tissue from

Figure 6–10 The Periosteum and Endosteum.

Select the correct words for the following sentence: The (endosteum/periosteum) covers the superficial layer of compact bone and is made up of (the fibrous and cellular layers/osteoblasts, osteoclasts, and osteocytes).

tendons and ligaments, as well as from the superficial periosteum, are called *perforating (Sharpey's) fibers*.

This method of attachment bonds the tendons and ligaments into the general structure of the bone, providing a much stronger attachment than would otherwise be possible. An extremely powerful pull on a tendon or ligament will usually break a bone rather than snap the collagen fibers at the bone surface.

The Endosteum

The **endosteum** (*endo-*, inside), an incomplete cellular layer, lines the medullary cavity (**Figure 6–10b**). This layer is active during bone growth, repair, and remodeling. It covers the trabeculae of spongy bone and lines the inner surfaces of the central canals of compact bone. The endosteum consists of a simple flattened layer of osteogenic cells that covers the bone matrix, generally without any intervening connective tissue fibers. Where the cellular layer is not complete, the matrix is exposed. At these exposed sites, osteoclasts and osteoblasts can remove or deposit matrix components.

Checkpoint

7. Compare the structures and functions of compact bone and spongy bone.
8. A sample of long bone has lamellae, which are not arranged in osteons. Is the sample most likely taken from the epiphysis or diaphysis?

See the blue Answers tab at the back of the book.

6-5 Bones form through ossification and enlarge through interstitial and appositional growth

Learning Outcome Compare the mechanisms of endochondral ossification and intramembranous ossification.

The growth of the skeleton determines the size and proportions of the body. In this section, we consider the physical processes of bone formation, or **ossification**, and bone growth. Ossification, or osteogenesis, refers specifically to the formation of bone. The process of **calcification**—the deposition of

Clinical Note Heterotopic Bone Formation

Heterotopic (*hetero-*, different + *topos*, place) **ossification (HO)** is the abnormal development of bone in nonskeletal tissues. This new bone grows at a rate that is three times faster than normal bone formation and is classified into three main types: myositis ossificans, traumatic myositis ossificans, and neurogenic heterotopic ossification. *Myositis ossificans* is a rare genetic form that causes ossification of the muscles. *Traumatic myositis ossificans* occurs in an area that has experienced repeated trauma or a single hard hit to soft tissue, or as a result of hip surgery. *Neurogenic heterotopic ossification* occurs frequently as a complication of spinal cord injury, but the pathophysiology is not fully understood. All forms are characterized by pain and decreased range of motion; treatment is problematic because any surgical intervention may trigger more ossification.

calcium salts—takes place during ossification, but it can also occur in other tissues. When calcification occurs in tissues other than bone, the result is a calcified tissue (such as calcified cartilage) that does not resemble bone.

Ossification occurs in two ways: endochondral and intramembranous. In *endochondral ossification*, bone replaces existing cartilage. Then bone growth occurs through interstitial growth (in length) and appositional growth (in width). In *intramembranous ossification*, bone develops directly from mesenchyme (loosely organized embryonic connective tissue) or fibrous connective tissue.

The bony skeleton begins to form about 6 weeks after fertilization, when the embryo is approximately 12 mm (0.5 in.) long. (At this stage, the existing skeletal elements are made of cartilage.) During fetal (beyond the eighth week) development, these cartilages are then replaced by bone, by either endochondral or intramembranous ossification. Endochondral ossification occurs mostly in long bones, while intramembranous ossification occurs mostly in flat bones.

During development after birth, the bones undergo a tremendous increase in size. Bone growth continues through adolescence, and portions of the skeleton generally do not stop growing until about age 25.

Endochondral Ossification

During development, most bones originate as hyaline cartilages that are miniature models of the corresponding bones of the adult skeleton. These cartilage models are gradually replaced by bone through the process of **endochondral** (en-dō-KON-drul) (*chondros*, cartilage) **ossification**. The steps

in limb bone development provide a good example of this process (**Spotlight Figure 6–11**). Please study steps 1–4 of this figure thoroughly now. Note that this process includes the development of a **primary ossification center** *inside* the cartilage model.

Growth in Length: Interstitial Growth

The process of interstitial growth is shown in steps 5–7 of **Spotlight Figure 6–11**. Please read through these steps carefully. Note that this process involves the development of **secondary ossification centers**.

The completion of epiphyseal growth is called **epiphyseal closure**. The timing of epiphyseal closure differs from bone to bone and from individual to individual. The toes may complete ossification by age 11, but parts of the pelvis or the wrist may continue to enlarge until about age 25. The timing of endochondral ossification can be monitored by comparing the width of the **epiphyseal cartilages** in successive x-rays. In adults, the former location of this cartilage can often be seen in x-rays as a narrow *epiphyseal line*, which remains after epiphyseal closure (**Figure 6–12**).

Growth in Width: Appositional Growth

A superficial layer of bone, or bone collar, forms early in endochondral ossification (**Spotlight Figure 6–11**, step 2). After that, the developing bone increases in diameter through **appositional growth** at the outer surface. In this process, cells of the inner layer of the periosteum differentiate into osteoblasts and deposit superficial layers of bone matrix. Eventually, these osteoblasts become surrounded by matrix and differentiate into osteocytes.

Over much of the surface, appositional growth adds a series of layers that form circumferential lamellae. In time, the deepest circumferential lamellae are recycled and replaced by osteons typical of compact bone. However, blood vessels and collagen fibers of the periosteum can sometimes become enclosed within the matrix produced by osteoblasts. Osteons may then form around the smaller vessels. While bone matrix is being added to the outer surface of the growing bone, osteoclasts are removing bone matrix at the inner surface, but at a slower rate. As a result, the medullary cavity gradually enlarges as the bone gets larger in diameter.

Intramembranous Ossification

Intramembranous (in-tra-MEM-bra-nus) **ossification** begins when osteoblasts differentiate from mesenchymal stem cells within mesenchymal or fibrous connective tissue. This type of ossification is also called *dermal ossification* because it normally takes place in the deeper layers of the dermis. The resulting bones are called *dermal bones*. Examples of dermal bones are the flat bones of the skull, the mandible (lower jaw), and the

Endochondral ossification begins with the formation of a hyaline cartilage model. This model serves as the pattern for almost all bone development. Limb bone development is a good example of this process. By the time an embryo is six weeks old, the proximal bones of the limbs, the humerus (upper limb) and femur (lower limb), have formed, but they are composed entirely of cartilage. These cartilage models continue to grow by expansion of the cartilage matrix (interstitial growth) and the production of more cartilage at the outer surface (appositional growth).

Initiation of Ossification in the Developing Bone (Steps 1–4)

- 1** As the cartilage enlarges, chondrocytes near the center of the shaft increase greatly in size. The matrix is reduced to a series of small struts that soon begin to calcify. The enlarged chondrocytes then die and disintegrate, leaving cavities within the cartilage.

- 2** Blood vessels grow around the edges of the cartilage, and the cells of the perichondrium convert to osteoblasts. The shaft of the cartilage then becomes ensheathed in a superficial layer of bone.

- 3** Blood vessels penetrate the cartilage and invade the central region. Fibroblasts migrating with the blood vessels differentiate into osteoblasts and begin producing spongy bone at a primary ossification center. Bone formation then spreads along the shaft toward both ends of the former cartilage model.

- 4** Remodeling occurs as growth continues, creating a medullary cavity. The osseous tissue of the shaft becomes thicker, and the cartilage near each epiphysis is replaced by shafts of bone. Further growth involves increases in length and diameter.

Increasing the Length of a Developing Long Bone (Steps 5–7)

During the initial stages of ossification, osteoblasts move away from the primary ossification center toward the epiphyses. But they do not complete the ossification of the model immediately, because the cartilages of the epiphyses continue to grow. The region where the cartilage is being replaced by bone lies at the metaphysis, the junction between the diaphysis and an epiphysis. On the diaphyseal (shaft) side of the metaphysis, osteoblasts continually invade the cartilage and replace it with bone, while on the epiphyseal side, new cartilage is produced at the same rate. The situation is like a pair of joggers, one in front of the other. As long as they are running at the same speed, they can run for miles without colliding. In this case, the osteoblasts and the epiphysis are both “running away” from the primary ossification center. As a result, the osteoblasts never catch up with the epiphysis, and the bone continues to grow longer and longer.

5

Capillaries and osteoblasts migrate into the epiphyses, creating secondary ossification centers.

6

The epiphyses eventually become filled with spongy bone. The metaphysis, a relatively narrow cartilaginous region called the **epiphyseal cartilage**, or *epiphyseal plate*, now separates the epiphysis from the diaphysis. On the shaft side of the metaphysis, osteoblasts continuously invade the cartilage and replace it with bone. New cartilage is produced at the same rate on the epiphyseal side.

Within the epiphyseal cartilage, the chondrocytes are organized into zones.

Chondrocytes at the epiphyseal side of the cartilage continue to divide and enlarge.

Chondrocytes degenerate at the diaphyseal side.

Osteoblasts migrate upward from the diaphysis and cartilage is gradually replaced by bone.

7

At puberty, the rate of epiphyseal cartilage production slows and the rate of osteoblast activity accelerates. As a result, the epiphyseal cartilage gets narrower and narrower, until it ultimately disappears. This event is called **epiphyseal closure**. The former location of the epiphyseal cartilage becomes a distinct **epiphyseal line** that remains after epiphyseal growth has ended.

A thin cap of the original cartilage model remains exposed to the joint cavity as the **articular cartilage**. This cartilage prevents damaging the joint from bone-to-bone contact.

Figure 6–12 Bone Growth at Epiphyseal Cartilages.**a** An x-ray of growing epiphyseal cartilages (arrows)**b** Epiphyseal lines in an adult (arrows)

clavicles (collarbones). The steps of intramembranous ossification are summarized in **Figure 6–13**. Please study each step before moving on.

Blood and Nerve Supplies to Bone

For bones to grow and be maintained, they require an extensive blood supply. For this reason, osseous tissue is highly vascular. In a typical bone such as the humerus, three major sets of blood vessels develop (**Figure 6–14**):

1. *The Nutrient Artery and Vein.* The blood vessels that supply the diaphysis form by invading the cartilage model as endochondral ossification begins. Most bones have only one *nutrient artery* and one *nutrient vein*, but a few bones, including the femur, have more than one of each. The vessels enter the bone through one or more round

passageways called *nutrient foramina* in the diaphysis. Branches of these large vessels form smaller perforating canals and extend along the length of the shaft into the osteons of the surrounding compact bone.

2. *Metaphyseal Vessels.* The *metaphyseal* (met-a-FIZ-ē-ul) vessels supply blood to the inner (diaphyseal) surface of each epiphyseal cartilage, where that cartilage is being replaced by bone.
3. *Periosteal Vessels.* Blood vessels from the periosteum provide blood to the superficial osteons of the shaft. During endochondral bone formation, branches of periosteal vessels also enter the epiphyses, providing blood to the secondary ossification centers.

Following the closure of the epiphyses, all three sets of vessels become extensively interconnected.

The periosteum also contains a network of lymphatic vessels (lymphatics) and sensory nerves. The lymphatics collect lymph from branches that enter the bone and reach individual osteons by the perforating canals. The sensory nerves penetrate the compact bone with the nutrient artery to innervate the endosteum, medullary cavity, and epiphyses. Because of the rich sensory innervation, injuries to bones are usually very painful.

In the next section, we examine the maintenance and replacement of mineral reserves in the adult skeleton.

Checkpoint

9. In endochondral ossification, what is the original source of osteoblasts?
10. During intramembranous ossification, which type of tissue is replaced by bone?
11. How could x-rays of the femur be used to determine whether a person has reached full height?

See the blue Answers tab at the back of the book.

6-6 Bone growth and development depend on bone remodeling, which is a balance between bone formation and bone resorption

Learning Outcome Describe the remodeling and homeostatic mechanisms of the skeletal system.

The process of **bone remodeling** continuously recycles and renews the organic and mineral components of the bone matrix. Bone remodeling goes on throughout life, as part of normal bone maintenance. Remodeling can replace the matrix but leave the bone unchanged, or it may change the shape, internal architecture, or mineral content of the bone. Through remodeling, older mineral deposits are removed from bone and released into the circulation while circulating minerals are being absorbed and deposited.

Figure 6–13 Intramembranous Ossification.

Figure 6–14 The Blood Supply to a Mature Bone.

Bone remodeling involves an interplay among the activities of osteocytes, osteoblasts, and osteoclasts. In adults, osteocytes are continuously removing and replacing the surrounding calcium salts. Osteoclasts and osteoblasts also remain active even after the epiphyseal cartilages have closed. Osteoclasts are constantly removing matrix, and osteoblasts are always adding to it. Normally, their activities are balanced: As quickly as osteoblasts form one osteon, osteoclasts remove another. The homeostatic balance between the opposing activities of osteoclasts and osteoblasts is very important. When osteoclasts remove calcium salts faster than osteoblasts deposit them, bones weaken. When osteoblast activity predominates, bones become stronger and more massive. This opposition causes some interesting differences in bone structure among individuals. People who subject their bones to muscular stress through weight training or strenuous exercise develop not only stronger muscles, but also stronger bones. Alternatively, declining

muscular activity due to immobility leads to reduced bone mass at sites of muscle attachment.

The turnover rate of bone is quite high. In young adults, almost 20% of the skeleton is recycled and replaced each year. However, not every part of every bone is affected equally. The rate of turnover differs regionally and even locally. For example, the spongy bone in the head of the femur may be replaced two or three times each year, but the compact bone along the shaft remains largely unchanged.

Because of their biochemical similarity to calcium, heavy-metal ions such as lead, strontium, cobalt, or radioactive uranium or plutonium can be incorporated into the matrix of bone. Osteoblasts do not differentiate between these heavy-metal ions and calcium. This means that any heavy metal ions present in the bloodstream will be deposited into the bone matrix. Some of these ions are potentially dangerous, and the turnover of bone matrix can have detrimental health effects as ions that are absorbed and accumulated are released into the circulation over a period of years.

Checkpoint

12. Describe bone remodeling.
13. Explain how heavy-metal ions could be incorporated into bone matrix.

See the blue Answers tab at the back of the book.

6-7 Exercise, nutrition, and hormones affect bone development and the skeletal system

Learning Outcome Discuss the effects of exercise, nutrition, and hormones on bone development and on the skeletal system.

What factors have the most important effects on the processes of bone remodeling? Exercise, nutrition, and hormones are key.

The Effects of Exercise on Bone

The turnover and recycling of minerals give each bone the ability to adapt to new stresses. The sensitivity of osteoblasts to electrical events has been theorized as the mechanism that controls the internal organization and structure of bone. Whenever a bone is stressed, the mineral crystals generate minute electrical fields. Osteoblasts are apparently attracted to these electrical fields and, once in the area, begin to produce bone. This finding has led to the successful use of small electric fields in stimulating bone healing.

Because of their adaptability, bone shapes reflect the forces applied to them. For example, bumps and ridges on the surface of a bone mark the sites where tendons are attached. If muscles become more powerful, the corresponding bumps and ridges enlarge to withstand the increased forces. Heavily

stressed bones become thicker and stronger, and bones that are not subjected to ordinary stresses become thin and brittle. For this reason, regular exercise is an important stimulus for maintaining normal bone structure. Champion weightlifters typically have massive bones with thick, prominent ridges. In nonathletes, moderate amounts of physical activity and weight-bearing activities are essential for stimulating normal bone maintenance and maintaining adequate bone strength.

Degenerative changes in the skeleton take place after relatively brief periods of inactivity. For example, a person may use a crutch to take weight off an injured leg while wearing a cast. After a few weeks, the unstressed bones can lose up to a third of their mass. When normal weight loading is resumed, the bones rebuild. In reality, it takes longer to rebuild bone than to lose bone density. However, the removal of calcium salts can be a serious health hazard both for astronauts remaining in a weightless environment and for bedridden or paralyzed patients who spend months or years without stressing their skeleton.

Nutritional and Hormonal Effects on Bone

Normal bone growth and maintenance depend on a combination of nutritional and hormonal factors, such as the following:

- **Minerals.** Normal bone growth and maintenance cannot take place without a constant dietary source of calcium and phosphorus. Lesser amounts of other minerals, such as magnesium, fluoride, iron, and manganese, are also required.
- **Calcitriol and Vitamin D₃.** The hormone *calcitriol* (kal-si-TRĪ-ol), synthesized in the kidneys, is essential for normal calcium and phosphate ion absorption in the digestive tract. Calcitriol is synthesized from a related steroid, *cholecalciferol* (kō-lē-kal-SIF-er-ol; vitamin D₃), which may be produced in the skin or absorbed from the diet.
- **Vitamin C.** An adequate level of vitamin C must be present in the diet. This vitamin, which is required for certain key enzymatic reactions in collagen synthesis, also stimulates osteoblast differentiation. One of the signs of vitamin C

deficiency—a condition called *scurvy*—is a loss of bone mass and strength.

- **Vitamins A, K, and B₁₂.** Three other vitamins have significant effects on bone structure. Vitamin A, which stimulates osteoblast activity, is particularly important for normal bone growth in children. Vitamins K and B₁₂ are required for the synthesis of proteins in normal bone.
- **Growth Hormone and Thyroxine.** *Growth hormone*, produced by the pituitary gland, and *thyroxine* (thĪ-ROK-sēn), from the thyroid gland, stimulate bone growth. Growth hormone stimulates protein synthesis and the rates of cell division and cell growth throughout the body. Thyroxine stimulates cell metabolism and increases the rate of osteoblast activity. In proper balance, these hormones maintain normal activity at the epiphyseal cartilages until puberty.
- **Sex Hormones.** At puberty, rising levels of sex hormones (*estrogen* in females and *testosterone* in males) stimulate osteoblasts to produce bone faster than the rate at which epiphyseal cartilage expands, leading to epiphyseal closure.

Differences in male and female sex hormones account for significant variations in body size and proportions. Because estrogen causes faster epiphyseal closure than does testosterone, females are generally shorter than males at maturity.

- **Parathyroid Hormone and Calcitonin.** *Parathyroid hormone*, from the parathyroid glands, has an important effect on bone, and to a much lesser extent, so does *calcitonin* (kal-si-TŌ-nin) from the C cells of the thyroid gland.

The major hormones affecting the growth and maintenance of the skeletal system are summarized in **Table 6–1**.

The skeletal system is unique in that it persists after life, providing hints about the sex, lifestyle, and environmental conditions experienced by the individual. Not only do the bones reflect the physical stresses placed on the body, but they also provide clues about a person's health and diet. By using the appearance, strength, and composition of bone, forensic scientists and physical anthropologists can detect

Table 6–1 Hormones Involved in Bone Growth and Maintenance

Hormone	Primary Source	Effect on Skeletal System
Calcitriol	Kidneys	Increases calcium and phosphate ion absorption by the intestines of the digestive tract
Growth hormone	Pituitary gland	Stimulates osteoblast activity and the synthesis of bone matrix
Thyroxine	Thyroid gland (follicle cells)	With growth hormone, stimulates osteoblast activity and the synthesis of bone matrix
Sex hormones	Ovaries (estrogen) Testes (testosterone)	Stimulate osteoblast activity and the synthesis of bone matrix; estrogen stimulates epiphyseal closure earlier than testosterone
Parathyroid hormone	Parathyroid glands	Stimulates osteoclast (and osteoblast) activity; increases the blood calcium ion level
Calcitonin	Thyroid gland (C cells)	In pregnant and nursing females, it decreases the blood calcium ion level and may aid calcium ion transfer to the fetus

features characteristic of hormonal deficiencies. By combining the physical clues from the skeleton with modern molecular techniques, such as DNA fingerprinting, a wealth of information can be learned.

✓ Checkpoint

See the blue Answers tab at the back of the book.

6-8 Calcium plays a critical role in bone physiology

Learning Outcome Explain the role of calcium as it relates to the skeletal system.

A dynamic relationship exists between calcium and the skeletal system, and hormones influence calcium balance in the body.

The Skeleton as a Calcium Reserve

A chemical analysis of bone reveals its importance as a mineral reserve (**Figure 6-15**). For the moment, we focus on the homeostatic regulation of calcium ion concentration in body fluids. (We consider other minerals in later chapters.) Calcium is the most abundant mineral in the human body. The typical human body contains 1–2 kg (2.2–4.4 lb) of calcium, with nearly 99% of it deposited in the skeleton.

By providing a calcium reserve, the skeleton plays the primary role in the homeostatic maintenance of a normal blood calcium ion concentration. This function can have a direct effect on the shape and strength of the bones in the skeleton. When large numbers of calcium ions are released from the bones, the bones become weaker. When calcium salts are deposited, the bones become denser and stronger.

Hormones and Calcium Ion Balance

Calcium ions play a role in a variety of physiological processes, so the body must tightly control the calcium ion concentration to prevent damage to essential physiological systems. Even small variations from the normal concentration affect cellular operations, and larger changes can cause a clinical crisis. Calcium ions are particularly important to both the plasma membranes and the intracellular activities of neurons and

+ Clinical Note Abnormal Bone Development

A variety of endocrine or metabolic problems can result in characteristic skeletal changes. In **pituitary growth failure**, inadequate production of growth hormone leads to reduced epiphyseal cartilage activity and abnormally short bones. This condition is becoming increasingly rare in the United States, because children can be treated with synthetic human growth hormone.

Gigantism results from an overproduction of growth hormone before puberty (**Photo a**). (The world record for height is 272 cm, or 8 ft, 11 in. It was reached by Robert Wadlow, of Alton, Illinois, who died at age 22 in 1940. Wadlow weighed 216 kg, or 475 lb.) If the growth hormone level rises abnormally after epiphyseal cartilages close, the skeleton does not grow longer. Instead, bones get thicker, especially in the face, jaw, and hands. Cartilage growth and alterations in soft-tissue structure lead to changes in physical features, such as the contours of the face. These physical changes take place in the disorder called **acromegaly** (ak-roh-MEG-ah-lē).

Several inherited metabolic conditions that affect many systems influence the growth and development of the skeletal system. These conditions produce characteristic variations in body proportions. For example, many individuals with **Marfan syndrome** are very tall and have long, slender limbs (**Photo b**).

The cause is excessive cartilage formation at the epiphyseal cartilages. The underlying mutation affects the structure of connective tissue throughout the body, and commonly causes cardiovascular events such as the sudden death of athletes during strenuous physical activity.

a Gigantism

b Marfan syndrome

Figure 6–15 A Chemical Analysis of Bone.

muscle cells, especially cardiac muscle cells. If the calcium ion concentration of body fluids increases by 30%, neurons and muscle cells become unresponsive. If the calcium ion level decreases by 35%, neurons become so excitable that convulsions can occur. A 50% reduction in calcium ion concentration generally causes death. Calcium ion concentration is so closely regulated, however, that daily fluctuations of more than 10% are highly unusual.

Two hormones with opposing effects maintain calcium ion homeostasis (**Figure 6–16**). These hormones, parathyroid hormone and calcitonin, coordinate the storage, absorption, and excretion of calcium ions. Three target sites and functions are involved: (1) bones (storage), (2) digestive tract (absorption), and (3) kidneys (excretion).

Figure 6–16a indicates factors that increase the calcium ion level in the blood. When the calcium ion concentration in the blood falls below normal, cells of the **parathyroid glands**, embedded in the thyroid gland in the neck, release **parathyroid hormone (PTH)** into the bloodstream. Parathyroid hormone has the following three major effects, all of which *increase* the blood calcium ion level:

- *Stimulating osteoclast activity (indirectly).* Osteoclasts do not have PTH receptors, but PTH binds to receptors on adjacent osteoblasts. This binding causes the osteoblasts to release an osteoclast differentiation factor called RANKL (receptor activator of nuclear factor- κ B). RANKL activates receptors on pre-osteoclast cells, which in turn causes them to differentiate into mature osteoclasts. These mature osteoclasts release enzymes that promote bone resorption, thereby releasing calcium ions into the bloodstream.
- *Increasing the amount of calcium ions absorbed by the intestines by enhancing calcitriol secretion by the kidneys.*

Under normal circumstances, calcitriol is always present, and parathyroid hormone controls its effect on the intestinal epithelium.

- *Decreasing the amount of calcium ions excreted by the kidneys.* This causes more calcium to remain in the bloodstream.

Under these conditions, *more* calcium ions enter body fluids, and *fewer* are lost. The calcium ion concentration increases to a normal level, and homeostasis is restored.

Calcitonin was discovered more than 50 years ago, but its role in human physiology remains unclear. Although calcitonin secretion is stimulated by increased blood calcium, it does not appear to cause bone deposition of calcium by osteoblasts. Its effects are restricted to osteoclasts, whose activity is reduced. The kidneys respond to calcitonin by excreting more calcium and secreting less calcitriol, which lessens calcium absorption by the intestines (**Figure 6–16b**). In pregnant and nursing females, both calcitonin and vitamin D₃ are increased, suggesting that these increases may be important in transferring maternal calcium to the fetus and for preserving and recovering bone mineral density in the female. Yet its exact mechanism of action remains elusive. Calcitonin is used as a treatment for osteoporosis in postmenopausal females. Pharmacological calcitonin is administered as a nasal spray, takes about 15 minutes to be absorbed into the blood, and can inhibit osteoclast activity in these females.

Changes in mineral content do not necessarily affect the shape of the bone because the bone matrix contains protein fibers as well as mineral deposits. In *osteomalacia* (os-tē-ō-ma-LĀ-shē-uh; *malakia*, softness), the bones appear normal, although they are weak and flexible due to poor mineralization. *Rickets*, a form of osteomalacia affecting children, generally results from a vitamin D₃ deficiency caused by inadequate skin exposure to sunlight and an

Figure 6–16 Homeostasis of Blood Calcium Ion Level.

What gland responds when the blood calcium level is too low?

inadequate dietary supply of the vitamin. The bones of children with rickets are so poorly mineralized that they become very flexible. The bones bend laterally, and affected individuals develop a bowlegged appearance because the walls of each femur can no longer resist the tension and compression forces applied by the body weight (**Figure 6–9**). In the United States, milk is fortified with vitamin D; this practice began in the 1930s to prevent rickets.

6-9 A fracture is a crack or break in a bone

Learning Outcome Describe the types of fractures and explain how fractures heal.

Despite its mineral strength, bone can crack or even break if it is subjected to extreme loads, sudden impacts, or stresses from unusual directions. The damage that results is called a **fracture**. Most fractures heal even after severe damage if the blood supply and the cellular components of the endosteum and periosteum survive. **Spotlight Figure 6–17** illustrates the different types of fractures and the repair process. Please study

this figure carefully before reading the next section. Note that the two main types of fractures are **open** (or compound) and **closed** (or simple).

✓ Checkpoint

19. List the four steps involved in fracture repair, beginning at the onset of the bone break.
20. At which point in fracture repair would there be an external callus?

See the blue Answers tab at the back of the book.

TYPES OF FRACTURES

Fractures are named by four basic either/or categories, each with two groupings: (1) position of bone ends (nondisplaced or displaced); (2) completeness of break (complete or incomplete); (3) orientation of break to the bone's long axis (linear or transverse); and (4) whether or not the broken bone penetrates the skin (open or closed).

Open (*compound*) fractures project through the skin. **Closed** (*simple*) fractures are completely internal. Open fractures tend to be more dangerous than closed due to an increased risk of infection or uncontrolled bleeding. In closed fractures, the bone ends can only be seen on x-ray because the skin remains intact.

Transverse fractures, such as this fracture of the ulna, break a bone shaft across its long axis.

Displaced fractures produce new and abnormal bone arrangements. **Nondisplaced fractures** retain the normal alignment of the bones or fragments.

Compression fractures occur in vertebrae subjected to extreme stresses, such as those produced by the forces that arise when you land on your seat in a fall. Compression fractures are often associated with osteoporosis.

Spiral fractures, such as this fracture of the femur, are produced by twisting stresses that spread along the length of the bone.

REPAIR OF A FRACTURE

1 Fracture hematoma formation.

Immediately after the fracture, extensive bleeding occurs. A large blood clot, or **fracture hematoma**, soon closes off the injured vessels and leaves a fibrous meshwork in the damaged area. The disruption of circulation kills local osteocytes, broadening the area affected. Dead bone soon extends along the shaft in either direction.

2 Callus formation.

The cells of the intact endosteum and periosteum undergo rapid cycles of cell division, and the daughter cells migrate into the fracture zone. An **internal callus** forms as a network of spongy bone unites the inner edges of the fracture. An **external callus** of cartilage and bone encircles and stabilizes the outer edges of the fracture.

Epiphyseal fracture

Comminuted fracture

Greenstick fracture

Colles fracture

Pott's fracture

Epiphyseal fractures, such as this fracture of the femur, tend to occur where the bone matrix is undergoing calcification and chondrocytes are dying. A clean transverse fracture along this line generally heals well. Unless carefully treated, fractures between the epiphysis and the epiphyseal cartilage can permanently stop growth at this site.

Comminuted fractures, such as this fracture of the femur, shatter the affected area into a multitude of bony fragments.

In a **greenstick fracture**, such as this fracture of the radius, only one side of the shaft is broken, and the other is bent. This type of fracture generally occurs in children, whose long bones have yet to ossify fully.

A **Colles fracture**, a break in the distal portion of the radius, is typically the result of reaching out to cushion a fall.

A **Pott's fracture**, also called a bimalleolar fracture, occurs at the ankle and affects both the medial malleolus of the distal tibia and the lateral malleolus of the distal fibula.

Internal callus

External callus

3 Spongy bone formation. As the repair continues, osteoblasts replace the central cartilage of the external callus with spongy bone, which then unites the broken ends. Fragments of dead bone and the areas of bone closest to the break are resorbed and replaced. The ends of the fracture are now held firmly in place and can withstand normal stresses from muscle contractions.

External callus

4 Compact bone formation.

A swelling initially marks the location of the fracture. Over time, this region will be remodeled by osteoblasts and osteoclasts, and little evidence of the fracture will remain. The repair may be "good as new" or the bone may be slightly thicker and stronger than normal at the fracture site. Under comparable stresses, a second fracture will generally occur at a different site.

6-10 Osteopenia has widespread effects on aging bones

Learning Outcome Summarize the effects of the aging process on the skeletal system.

The bones of the skeleton become thinner and weaker as a normal part of the aging process. Inadequate ossification is called **osteopenia** (os-tē-ō-PĒ-nē-uh; *penia*, lacking). All of us become slightly osteopenic as we age. This reduction in bone mass begins between ages 30 and 40. At this age, osteoblast activity begins to decrease, while osteoclast activity continues at the previous level. Once the reduction begins, females lose about 8% of their skeletal mass every decade. Males lose less—about 3% per decade. Not all parts of the skeleton are equally affected. Epiphyses, vertebrae, and the jaws lose more mass than other sites, resulting in fragile limbs, reduction in height, and loss of teeth.

When the reduction in bone mass is sufficient to compromise normal function, the condition is known as **osteoporosis** (os-tē-ō-po-RŌ-sis; *porosus*, porous). The brittle, fragile bones that result are likely to break when exposed to stresses that younger individuals could easily tolerate. For example, a hip fracture can occur when a 90-year-old person simply tries to stand. Any fractures in older individuals lead to a loss of independence and immobility that further weakens the skeleton. The extent of the loss of spongy bone mass due to osteoporosis is shown in **Figure 6-18**. The reduction in compact bone mass is equally severe.

Sex hormones are important in maintaining normal rates of bone deposition. As hormone levels decrease, bone mass also diminishes. Over age 45, an estimated 29% of females and 18% of males have osteoporosis. In females, the condition accelerates after menopause, due to a decrease in circulating estrogen. Severe osteoporosis is less common in males under age 60 than in females of that same age group because males continue to produce testosterone until late in life.

Osteoporosis can also develop as a secondary effect of many cancers. Cancers of the bone marrow, breast, or other tissues release a chemical known as **osteoclast-activating factor**. It increases both the number and activity of osteoclasts and produces severe osteoporosis.

Figure 6-18 The Effects of Osteoporosis on Spongy Bone.

Normal spongy bone

SEM × 25

Spongy bone in osteoporosis

SEM × 21

Checkpoint

21. Define osteopenia.
22. Why is osteoporosis more common in older females than in older males?

See the blue Answers tab at the back of the book.

6 Chapter Review

Study Outline

An Introduction to Bones and Bone Tissue

1. The skeletal system has a variety of purposes, such as providing a framework for body posture while also allowing for precise movements.

6-1 The skeletal system has several major functions

2. The skeletal system includes the bones of the skeleton and the cartilages, ligaments, and other connective tissues that stabilize or connect the bones. Major functions of the skeletal system include support, storage of minerals and lipids, blood cell production, protection, and leverage.

6-2 Bones are classified according to shape and structure, and they have a variety of bone markings

3. Bones may be categorized as **sutural bones** (*Wormian bones*), **irregular bones**, **short bones**, **flat bones**, **long bones**, and **sesamoid bones**. (*Figure 6-1*)
4. Each bone has characteristic **bone markings**, or *surface features*, including projections, openings, and depressions. (*Figure 6-2*)
5. A representative long bone has a **diaphysis**, **epiphyses**, **metaphyses**, and a **medullary cavity**. (*Figure 6-3*)
6. The two types of bone tissue are **compact bone** and **spongy bone** (*trabecular bone*).
7. The medullary cavity and spaces within spongy bone contain either **red bone marrow** (for blood cell formation) or **yellow bone marrow** (for lipid storage).

6-3 Bone is composed of matrix and several types of cells: osteogenic cells, osteoblasts, osteocytes, and osteoclasts

8. Bone tissue is a supporting connective tissue with a solid matrix. Except at joint surfaces, a dense layer of connective tissue called *periosteum* surrounds bones.
9. Bone matrix consists largely of calcium salts that form crystals of **hydroxyapatite**. A bone without a calcified matrix is very flexible. (*Figure 6-4*)
10. Osteogenic cells differentiate into osteoblasts. **Osteoblasts** synthesize new bone matrix by **osteogenesis** or **ossification**. **Osteocytes** are mature bone cells located in lacunae. Adjacent osteocytes are interconnected by **canaliculi**. They maintain the surrounding matrix and assist bone repair. **Osteoclasts** dissolve the bony matrix through **osteolysis**. (*Figure 6-5*)

6-4 Compact bone contains parallel osteons, and spongy bone contains trabeculae

11. The basic functional unit of compact bone is the **osteon**, containing osteocytes arranged around a **central canal**. **Perforating canals** extend perpendicularly to the bone surface. (*Figures 6-6, 6-7*)
12. Bone matrix forms layers called **lamellae**. *Concentric lamellae* surround an osteon. (*Figure 6-7*)

Media Resources:

- Chapter Quizzes, Chapter Practice Test, MP3 Tutor Sessions, and Clinical Case Studies
- Practice Anatomy Lab
- Interactive Physiology
- SmartArt Videos
- A&P Flix
- PhysioEx

13. Spongy bone contains **trabeculae**, typically in an open network. (*Figure 6-8*)
14. Compact bone is located where stresses come from a limited range of directions, such as along the diaphysis of long bones. Spongy bone is located where stresses are few or come from many directions, such as at the epiphyses of long bones. (*Figure 6-9*)
15. A bone is covered by a **periosteum** and lined with an **endosteum**. (*Figure 6-10*)

6-5 Bones form through ossification and enlarge through interstitial and appositional growth

16. Ossification (or *osteogenesis*) is the process of bone formation. **Calcification** is the process of depositing calcium salts within a tissue.
17. Endochondral ossification begins with a cartilage model that is gradually replaced by bone at the metaphysis. In this way, bone length increases. (*Spotlight Figure 6-11*)
18. The ends of the cartilage model remain as **articular cartilages**. (*Spotlight Figure 6-11*)
19. The timing of *epiphyseal closure* of the **epiphyseal cartilage** and the formation of an **epiphyseal line** differs among bones and among individuals. (*Spotlight Figure 6-11, Figure 6-12*)
20. Bone diameter increases through **appositional growth**.
21. Intramembranous ossification begins when osteoblasts differentiate within connective tissue. The process produces dermal bones. Such ossification begins at an **ossification center**. (*Figure 6-13*)
22. Three major sets of blood vessels provide an extensive supply of blood to bone. (*Figure 6-14*)

6-6 Bone growth and development depend on bone remodeling, which is a balance between bone formation and bone resorption

23. The organic and mineral components of bone are continuously recycled and renewed through **bone remodeling**, which involves interplay among the activities of osteocytes, osteoblasts, and osteoclasts.

6-7 Exercise, nutrition, and hormones affect bone development and the skeletal system

24. The shapes and thicknesses of bones reflect the stresses applied to them. For this reason, regular exercise is important in maintaining normal bone structure.
25. Normal ossification requires a reliable source of minerals, vitamins, and hormones.

26. *Growth hormone* and *thyroxine* stimulate bone growth. Parathyroid hormone and, to a lesser extent, calcitonin control blood calcium levels. (Table 6-1)

6-8 Calcium plays a critical role in bone physiology

27. Calcium is the most abundant mineral in the human body; about 99% of it is in the skeleton. (Figure 6-15)
28. Interactions among the bones, intestines of the digestive tract, and kidneys affect the calcium ion concentration. (Figure 6-16)
29. Parathyroid hormone (PTH) is the main hormone that regulates calcium ion homeostasis. PTH increases calcium ion

level in the blood. During pregnancy and nursing, calcitonin aids calcium ion transfer to the fetus and preserves bone mineral density in the female. (Figure 6-16)

6-9 A fracture is a crack or break in a bone

30. A break or crack in a bone is a **fracture**. The repair of a fracture involves the formation of a **fracture hematoma**, an **external callus**, and an **internal callus**. (Spotlight Figure 6-17)

6-10 Osteopenia has widespread effects on aging bones

31. The effects of aging on the skeleton include **osteopenia** and **osteoporosis**. (Figure 6-18)

Review Questions

See the blue Answers tab at the back of the book.

LEVEL 1 Reviewing Facts and Terms

- During embryonic development, the bony skeleton begins to form (a) at about 6 weeks, (b) in the first week, (c) at about 12 weeks, (d) at fertilization.
- All humans have at least two sesamoid bones in the form of small shallow dishes called (a) parietal bones, (b) patellae, (c) clavicles, (d) carpal bones.
- A meatus is (a) a deep furrow, (b) the opening of a canal, (c) a prominent ridge, (d) a chamber within a bone.
- The sternum is an example of a(n) (a) flat bone, (b) short bone, (c) long bone, (d) sesamoid bone, (e) irregular bone.
- The element *not* present in bones is (a) calcium, (b) sodium, (c) magnesium, (d) iron.
- At maturity, women are generally shorter than men because of the action of (a) estrogen, (b) testosterone, (c) growth hormone, (d) thyroxine.
- Classify the bone shapes in the following diagram according to their shape.

(a) _____	(b) _____
(c) _____	(d) _____
(e) _____	(f) _____

- What is *not* a function performed by osteocytes? (a) maintaining the mineral content of the bone matrix, (b) helping repair the damaged bone, (c) maintaining the protein content of the bone matrix, (d) division of cells, (e) communication between osteocytes.
- The hormone which is responsible for diminishing the calcium level in the blood of pregnant and nursing women is (a) estrogen, (b) parathyroid hormone, (c) calcitonin, (d) testosterone.
- The cells which dissolve the bony matrix in osteolysis are (a) osteocytes, (b) osteoclasts, (c) osteoblasts, (d) osteons, (e) osseous matrix cells.
- Name the major functions of the skeletal system.
- What is meant by the term *diploë*?
- What is a sinus in a bone?
- What is the difference between the periosteum and the endosteum regarding their structural compositions?
- List the inorganic components of the bone which contain 50 percent or more of the body's stock of that component.
- (a) What nutritional factors are essential for normal bone growth and maintenance? (b) What hormonal factors are necessary for normal bone growth and maintenance?
- Which three organs or tissues interact to assist in the regulation of calcium ion concentration in body fluids?
- Why are bone injuries usually extremely painful?

LEVEL 2 Reviewing Concepts

- How is blood circulation in an osteon organized?
- In the body, there are several forms of ossification. What is the final result of the process involved in the formation of a dermal bone?
- Is there a relation between some forms of cancer and osteoporosis?
- How does calcitonin help in maintaining appropriate calcium levels in pregnant women and their fetuses?
- Why would a physician be concerned about the growth patterns of a young child request an x-ray of the hand?
- What is a greenstick fracture, and why does it occur commonly in children?
- The process of bone growth at the epiphyseal cartilage is similar to (a) intramembranous ossification, (b) endochondral ossification, (c) the process of osteopenia, (d) the process of healing a fracture, (e) the process of calcification.
- How might bone markings be useful in identifying the remains of an individual who was shot and killed years ago?

LEVEL 3 Critical Thinking and Clinical Applications

27. While playing on her swing set, 10-year-old Reba falls and breaks her right leg. At the emergency room, the doctor tells her parents that the proximal end of the tibia where the epiphysis meets the diaphysis is fractured. The fracture is properly set and eventually heals. During a routine physical when she is 18, Reba learns that her right leg is 2 cm shorter than her left, probably because of her accident. What might account for this difference?
28. Inadequate secretion of which hormone results in reduced epiphyseal cartilage activity and abnormally short bones in children? (a) growth hormone, (b) calcitriol, (c) thyroxine, (d) parathyroid hormone, (e) calcitonin.
29. Monty does not enter puberty until he is 16. What effect would this have on his height? (a) Monty will probably be taller than if he had started puberty earlier. (b) Monty will probably be shorter than if he had started puberty earlier. (c) Monty will probably have a condition known as dwarfism. (d) Monty will have bones that are heavier than normal. (e) The late onset of puberty will have no effect on Monty's stature.
30. John and Boris are astronauts working in the ISS space station. It is their ambition to break the record of the longest stay in space. Could this be hazardous to their health?

**CLINICAL CASE Wrap-Up A Case of Child Abuse?**

Alex and his mother both have *osteogenesis imperfecta (OI)*, which means the imperfect formation of bone. Osteogenesis imperfecta is the most commonly inherited connective tissue disorder in the United States. The inherited defective gene codes for collagen that is made by osteoblasts and released into the bone matrix. This collagen is critical for bone strength, and it is also important in forming teeth, ligaments, and the whites of the eyes. There are several types of osteogenesis imperfecta with varying severities, but the Otero family has the most common, relatively mild type.

Without enough normal collagen in the bone matrix, the bones are brittle and fracture easily, often with minimal trauma. In more severe cases, the skeleton is not strong enough to support the body's weight. Patients with osteogenesis

imperfecta have characteristic heart-shaped faces, and the whites of their eyes have a blue tint. Hearing loss often accompanies the condition. Because of the way that this bone disorder is inherited, each of Alex's children will have a 50% chance of inheriting osteogenesis imperfecta.

Osteogenesis imperfecta seems to have affected people throughout history. An Egyptian mummy dating from 1000 BCE has been found with evidence of osteogenesis imperfecta.

1. Imagine a piece of Alex's tibia under the microscope. What does it look like before the fracture?
2. Should Alex continue playing soccer? Explain.

See the blue Answers tab at the back of the book.

6

Related Clinical Terms

achondroplasia: A disorder of bone growth that causes the most common type of dwarfism.

bone marrow transplant: Transferring healthy bone marrow stem cells from one person into another, replacing bone marrow that is either dysfunctional or has been destroyed by chemotherapy or radiation.

bone mineral density (BMD) test: A test to predict the risk of bone fractures by measuring how much calcium and other types of minerals are present in the patient's bones.

bone scan: A nuclear scanning test that identifies new areas of bone growth or breakdown. Used to evaluate damage, find cancer in the bones, and/or monitor the bone's conditions (including infection and trauma).

closed reduction: The correction of a bone fracture by manipulation without incision into the skin.

dual-energy x-ray absorptiometry (DEXA): Procedure that uses very small amounts of radiation to measure changes in bone density as low as 1%; the test monitors bone density in osteoporosis and osteopenia.

open reduction: The correction of a bone fracture by making an incision into the skin and rejoining the fractured bone parts, often by mechanical means such as a rod, plate, or screw.

orthopedics: The branch of medicine dealing with the correction of deformities of bones or muscles.

osteogenesis imperfecta (OI): An inherited (genetic) disorder characterized by extreme fragility of the bones; also called *brittle bone disease*.

osteomyelitis: An acute or chronic bone infection.

osteopetrosis: A rare hereditary bone disorder in which the bones become overly dense; it presents in one of three forms: osteopetrosis tarda, osteopetrosis congenita, and "marble bone" disease.

osteosarcoma: A type of cancer that starts in the bones; also called osteogenic sarcoma.

Paget's disease: A chronic disorder that can result in enlarged and misshapen bones due to abnormal bone destruction and regrowth.

traction: The application of a sustained pull on a limb or muscle to maintain the position of a fractured bone until healing occurs or to correct a deformity.

7

The Axial Skeleton

Learning Outcomes

These Learning Outcomes correspond by number to this chapter's sections and indicate what you should be able to do after completing the chapter.

- 7-1 ■ Identify the bones of the axial skeleton and describe their general functions.
- 7-2 ■ Identify the bones, foramina, and fissures of the cranium and face, and explain the significance of the markings on the individual bones.
- 7-3 ■ Describe the structure and functions of the orbital complex, nasal complex, and paranasal sinuses.
- 7-4 ■ Describe the key structural differences among the skulls of infants, children, and adults.
- 7-5 ■ Identify and describe the curves of the spinal column and indicate the function of each.
- 7-6 ■ Identify the five vertebral regions and describe the distinctive structural and functional characteristics of the vertebrae in each region.
- 7-7 ■ Explain the significance of the joints between the thoracic vertebrae and ribs, and between the ribs and sternum.

CLINICAL CASE Knocked Out

Dr. Deb Grady, a member of the American Board of Ringside Medicine, is covering a Golden Gloves boxing event as the ringside physician. She is closely watching a match between two older teenage boys. Up to the third round the fighters seem to be evenly matched. Suddenly, Dr. Grady witnesses a crushing punch delivered to the face of one fighter, knocking him out cold.

Dr. Grady jumps into the ring and carefully rolls the fighter over. She sees immediate and alarming swelling and bruising of the soft tissues around his left eye and profuse bleeding from a cut over that eye. As the young boxer regains consciousness, he sputters and coughs. Dr. Grady feels crackling

subcutaneous air (like popping bubble wrap) in the expanding soft tissues around his eye. “How many fingers am I holding up?” she asks the fighter, holding up her index finger. “Two,” the confused fighter answers. He is seeing double. “Follow my finger,” she instructs, moving her finger up to the level of his forehead. The fighter can track her finger with his right eye, but his injured left eye remains looking straight ahead.

Dr. Grady calls the fight off and accompanies the young boxer to the closest emergency room. **What has happened**

to the boxer’s left eye? To find out, turn to the Clinical Case Wrap-Up at the end of the chapter.

7

An Introduction to the Divisions of the Skeleton

The human skeleton has two main divisions, axial and appendicular. The **axial skeleton**, the bones of the head and trunk, forms the longitudinal axis of the body (**Figure 7-1**). The **appendicular skeleton** includes the bones that support and form the limbs. In this chapter, we turn our attention to the functional anatomy of the axial skeleton; in Chapter 8 we examine the appendicular skeleton.

7-1 The 80 bones of the head and trunk make up the axial skeleton

Learning Outcome Identify the bones of the axial skeleton and describe their general functions.

The axial skeleton has 80 bones, about 40% of the bones in the human body:

- the **skull** (8 *cranial bones* and 14 *facial bones*),
- the bones associated with the skull (6 *auditory ossicles* and the *hyoid bone*),
- the **thoracic cage** (the *sternum* and 24 *ribs*), and
- the **vertebral column** (24 *vertebrae*, the *sacrum*, and the *coccyx*).

The axial skeleton provides a framework that supports and protects the brain, the spinal cord, and the thoracic and abdominal organs. It also provides an extensive surface area for the attachment of muscles that (1) adjust the positions of the head, neck, and trunk; (2) perform breathing movements; and (3) stabilize or position parts of the appendicular skeleton. Note that the axial skeleton does not include the clavicles (collar bones) or

scapulae (shoulder blades), or the bones of the pelvic girdle (hip bones). The joints of the axial skeleton allow limited movement, but they are very strong and heavily reinforced with ligaments.

Checkpoint

1. Identify the bones of the axial skeleton.
2. List the primary functions of the axial skeleton.

See the blue Answers tab at the back of the book.

7-2 The skull’s 8 cranial bones protect the brain, and its 14 facial bones form the mouth, nose, and orbits

Learning Outcome Identify the bones, foramina, and fissures of the cranium and face, and explain the significance of the markings on the individual bones.

The **skull** contains 22 bones: 8 form the **cranium**, and 14 are associated with the face (**Figures 7-2, 7-3**).

Cranial, Facial, and Associated Bones

The eight **cranial bones** enclose the **cranial cavity**, a chamber that supports the brain (**Figure 7-2a, Spotlight Figure 7-4**). The *occipital* (ok-SIP-e-tul), right and left *parietal* (pa-RĪ-e-tul), and *frontal bones* form the **calvaria** (kal-VA-rē-uh), or *skullcap*. Blood vessels, nerves, and membranes that stabilize the brain’s position are attached to the inner surface of the cranium. Its outer surface provides an extensive area for the attachment of muscles that move the eyes, jaws, and head.

In addition, seven other bones are associated with the skull: six *auditory ossicles*, involved with hearing, and the *hyoid bone*, which supports the voice box (**Figure 7-2c**).

Figure 7–1 The Axial Skeleton.

- a** An anterior view of the entire skeleton, with the axial components highlighted. The numbers in the boxes indicate the number of bones in the adult skeleton.

- b** Anterior (top) and posterior (bottom) views of the axial skeleton. The individual bones associated with the skull are not visible.

Figure 7-2 Cranial and Facial Subdivisions of the Skull.

Joints, or *articulations*, form where two or more bones connect. A joint between the occipital bone of the skull and the first vertebra of the neck stabilizes the positions of the brain and spinal cord. The joints between the vertebrae of the neck permit a wide range of head movements.

Sutures

The connections between most of the skull bones of adults are immovable joints called **sutures** (SŪ-cherz). (An exception is the freely movable joint where the mandible contacts the cranium.) At a suture, bones are tied firmly together with dense fibrous connective tissue. The names of the four major sutures are as follows:

- **Lambdoid Suture.** The **lambdoid** (LAM-doyd) **suture** arches across the posterior surface of the skull (**Figure 7-3a**). This suture connects the occipital bone with the two parietal bones. One or more

sutural bones (*Wormian bones*) may be present along the lambdoid suture.

- **Coronal Suture.** The **coronal suture** attaches the frontal bone to the parietal bones of either side (**Figure 7-3b**). A cut through the body that parallels the coronal suture produces a *frontal*, or *coronal*, section (**Figure 1-6**).
- **Sagittal Suture.** The **sagittal suture** extends from the lambdoid suture to the coronal suture, between the parietal bones (**Figure 7-3b**). A cut along the midline of this suture produces a *midsagittal section*. A slice that parallels the sagittal suture produces a *parasagittal section*.
- **Squamous Sutures.** A **squamous** (SKWĀ-mus) **suture** on each side of the skull joins the temporal bone and the parietal bone of that side. **Figure 7-3a** shows the intersection between the squamous sutures and the lambdoid suture. **Figure 7-3c** shows the path of the squamous suture on the right side of the skull.

Figure 7-3 The Adult Skull.

Foramen or Fissure

Major Structures Using Passageway

Frontal Bone

Supra-orbital foramen	- Supra-orbital nerve (branch of CN V) - Supra-orbital artery
------------------------------	--

Sphenoid

Optic canal	- Optic nerve (II) - Ophthalmic artery
Superior orbital fissure	Oculomotor nerve (III), trochlear nerve (IV), ophthalmic branch of trigeminal nerve (V), and abducens nerve (VI)
Inferior orbital fissure	Maxillary division (V_2) of trigeminal nerve (V)

Maxilla

Infra-orbital foramen	- Infra-orbital nerve, branch of maxillary nerve (V_2) - Infra-orbital artery
------------------------------	---

Mandible

Mental foramen	- Mental nerve, branch of mandibular nerve (V_3) - Mental vessels
-----------------------	---

Sphenoid

Foramen lacerum (with temporal and occipital bones)	- Internal carotid artery after leaving carotid canal - Auditory tube
Foramen ovale	Mandibular division (V_3) of trigeminal nerve (V)

Temporal Bone

External acoustic meatus	Air in meatus conducts sound to eardrum
Carotid canal	Internal carotid artery
Stylomastoid foramen	Facial nerve (V)

Occipital Bone

Foramen magnum	- Medulla oblongata (most caudal portion of brain) - Accessory nerve (XI) - Vertebral arteries
Jugular foramen (with temporal bone)	- Glossopharyngeal, vagus, and accessory nerves (IX, X, XI) - Internal jugular vein

Looking at all the views of the skull, name the major sutures.

THE CRANIAL CAVITY

This sagittal section of the skull was taken just lateral to the nasal septum. It gives the best view of the cranial cavity. The colored boxes highlight the bones that surround the cranial cavity, and some of their key markings are highlighted within their respective boxes.

THE FLOOR OF THE CRANIUM

This superior view of a horizontal section through the skull shows the floor of the cranial cavity. This is where most of the nerves and blood vessels enter or leave the cranial cavity. Compare this figure and chart with *Figure 7–3e* showing the inferior view of the skull and *Figure 14–18* showing the origin of the cranial nerves.

b Horizontal section

Understanding skull structure will be especially important to you in later chapters when you study the nervous and cardiovascular systems.

Foramen or Fissure

Major Structures Using Passageway

Ethmoid

Olfactory foramina

- Olfactory nerve (I)

Sphenoid

Optic canal

- Optic nerve (II)
- Ophthalmic artery

Foramen rotundum

- Maxillary division (V_2) of trigeminal nerve (V)

Foramen lacerum

- Internal carotid artery after leaving carotid canal
- Auditory tube

Foramen ovale

- Mandibular division (V_3) of trigeminal nerve (V)

Foramen spinosum

- Blood vessels to membranes around central nervous system

Temporal Bone

Carotid canal

- Internal carotid artery

Internal acoustic meatus

- Vestibulocochlear nerve (VIII)
- Internal acoustic artery
- Facial nerve (VII)

Occipital Bone

Foramen magnum

- Medulla oblongata (most caudal portion of brain)
- Accessory nerve (XI)
- Vertebral arteries

Hypoglossal canal

- Hypoglossal nerve (XII)

Jugular foramen (with temporal bone)

- Glossopharyngeal, vagus, and accessory nerves (IX, X, XI)
- Internal jugular vein

FOCUS

The Individual Bones of the Skull

Let's explore the surface features of these bones further. Foramina and fissures create passages for blood vessels and nerves. The blood vessels are detailed in Chapter 21. The nerves are described in the Focus on cranial nerves in Chapter 14.

Cranial Bones

The Occipital Bone (Figure 7-5a)

General Functions: The **occipital bone** forms much of the posterior and inferior surfaces of the cranium.

Joints: The occipital bone articulates with the parietal bones, the temporal bones, the sphenoid, and the first cervical vertebra (the atlas) (Figure 7-3a,b,c,e and Spotlight Figure 7-4).

Regions/Markings (Figure 7-5a): The **external occipital protuberance** is a small bump at the midline on the inferior surface.

The **external occipital crest** begins at the external occipital protuberance. This crest marks the attachment of a ligament (*ligamentum nuchae*) that helps stabilize the vertebrae of the neck.

The **occipital condyles** are the sites of articulation between the skull and the first vertebra of the neck.

The *inferior* and *superior nuchal* (NŪ-kul) *lines* are ridges that intersect the external occipital crest. They mark the attachment sites of muscles and ligaments that stabilize the joints at the occipital condyles and balance the weight of the head over the vertebrae of the neck.

The concave internal surface of the occipital bone (Spotlight Figure 7-4a) closely follows the contours of the

brain. The grooves follow the paths of major blood vessels, and the ridges mark the attachment sites of membranes that stabilize the position of the brain.

Foramina: The **foramen magnum** (Spotlight Figure 7-4b) connects the cranial cavity with the vertebral canal, which is enclosed by the vertebral column. This foramen surrounds the connection between the brain and spinal cord.

The **jugular foramen** lies between the occipital bone and the temporal bone (Figure 7-3e). The *internal jugular vein* passes through this foramen, carrying venous blood from the brain.

The **hypoglossal canals** (Spotlight Figure 7-4b) begin at the lateral base of each occipital condyle and end on the inner surface of the occipital bone near the foramen magnum. The *hypoglossal nerves*, cranial nerves that control the tongue muscles, pass through these canals.

The Parietal Bones (Figure 7-5b)

General Functions: The paired **parietal bones** form part of the superior and lateral surfaces of the cranium.

Joints: The parietal bones articulate with one another and with the occipital, temporal, frontal, and sphenoid bones (Figure 7-3a,b,c,d and Spotlight Figure 7-4).

Regions/Markings: The *superior* and *inferior temporal lines* are low ridges that mark the attachment sites of the *temporalis*, a large muscle that closes the mouth (Figure 7-5b).

Grooves on the inner surface of the parietal bones mark the paths of cranial blood vessels (Spotlight Figure 7-4a).

Figure 7-5 The Occipital and Parietal Bones.

a Occipital bone, inferior view

b Right parietal bone, lateral view

The Frontal Bone (Figure 7-6)

General Functions: The **frontal bone** forms the anterior portion of the cranium and the roof of the *orbits* (eye sockets). Mucus from the *frontal sinuses* within this bone helps to flush the surfaces of the nasal cavities.

Joints: The frontal bone articulates with the parietal, sphenoid, ethmoid, nasal, lacrimal, maxillary, and zygomatic bones (Figure 7-3b,c,d,e and Spotlight Figure 7-4).

Regions/Markings: The **forehead** forms the anterior, superior portion of the cranium. It provides surface area for the attachment of facial muscles. The *superior temporal line* is continuous with the superior temporal line of the parietal bone.

The **supra-orbital margin** is a thickening of the frontal bone that helps protect the eye. The **glabella** (*glabellus*, smooth) is the area that is between the supra-orbital margins and superior to the nasal bones. It marks the most forward projection of the frontal bone.

The **lacrimal fossa** on the superior and lateral surface of the orbit is a shallow depression that marks the location of the *lacrimal* (tear) *gland*. Tears from this gland lubricate the surface of the eye.

The **frontal sinuses** are extremely variable in size and time of appearance. They generally appear after age 6, but some

people never develop them. We describe the frontal sinuses and other sinuses of the cranium and face in Section 7-3.

Foramina: The **supra-orbital foramen** provides passage for blood vessels that supply the eyebrow, eyelids, and frontal sinuses. In some cases, this foramen is incomplete. The blood vessels then cross the orbital rim within a **supra-orbital notch**.

Remarks: During development, the bones of the cranium form by the fusion of separate centers of ossification. At birth, these fusion processes are not yet complete: Two frontal bones articulate along the *frontal suture*. The suture generally disappears by age 8 as the bones fuse. In rare cases, it persists as the *metopic suture* and runs through the midline of the forehead. It is sometimes mistaken for a frontal bone fracture.

The Temporal Bones (Figure 7-7)

General Functions: The paired **temporal bones** (1) form part of both the lateral walls of the cranium and the *zygomatic arches*, (2) form the only joints with the mandible, (3) surround and protect the sense organs of the internal ear, and (4) are attachment sites for muscles that close the jaws and move the head.

Joints: The temporal bones articulate with the zygomatic, sphenoid, parietal, and occipital bones of the cranium and with the mandible (Figure 7-3 and Spotlight Figure 7-4).

Figure 7-6 The Frontal Bone.

Regions/Markings: The **squamous part** of the temporal bone is the lateral portion that borders the squamous suture. The concave, internal surface parallels the surface of the brain and is called the *cerebral surface*.

The **zygomatic process**, inferior to the temporal squamous part (**Figure 7-7a**), articulates with the *temporal process* of the zygomatic bone.

Together, these processes form the **zygomatic arch** (**Figure 7-3c,e**).

The **mandibular fossa** on the inferior surface marks the site of articulation with the mandible.

The **mastoid process** (**Figure 7-7b,c**) is an attachment site for muscles that rotate or extend the head. It contains *mastoid cells* (also called mastoid air cells), small, interconnected enclosed spaces that connect to the middle ear cavity. *Mastoiditis*, inflammation and infection in the air cell system, develops if pathogens reach the mastoid process. Signs and symptoms include severe earaches, fever, and swelling behind the ear.

The **styloid** (STĪ-loyd; *stylos*, pillar) **process**, near the base of the mastoid process, is attached to ligaments that support the hyoid bone and to the tendons of several muscles associated with the hyoid bone, the tongue, and the pharynx (throat).

The **petrous part** of the temporal bone, located on its internal surface, encloses the structures of the *internal ear*—sense

organs that provide information about hearing and balance (**Figure 7-7a**).

The **auditory ossicles** are in the *tympanic cavity*, or *middle ear*, a cavity within the petrous part. These tiny bones—three on each side—transfer sound vibrations from the delicate *tympanic membrane*, or eardrum, to the internal ear. (We discuss these bones and their functions in Chapter 17.)

Foramina (**Figure 7-3e**): The jugular foramen, between the temporal and occipital bones, provides passage for the internal jugular vein.

The **carotid canal** provides passage for the internal carotid artery, a major artery to the brain. As it leaves the carotid canal, the internal carotid artery passes through the anterior portion of the foramen lacerum.

The **foramen lacerum** (LAS-er-um; *lacerare*, to tear) is a jagged slit extending between the sphenoid and the petrous part of the temporal bone. This slit contains hyaline cartilage and small arteries that supply the inner surface of the cranium.

The **auditory tube** is an air-filled passageway that connects the pharynx (throat) to the middle ear. This tube passes through the posterior portion of the foramen lacerum.

The **external acoustic meatus** on the lateral surface, ends at the tympanic membrane, or eardrum (which disintegrates during the preparation of a dried skull).

Figure 7-7 The Temporal Bones.

The **stylomastoid foramen** lies posterior to the base of the styloid process. The *facial nerve* passes through this foramen to control the facial muscles.

The **internal acoustic meatus** begins on the medial surface of the petrous part of the temporal bone. It carries blood vessels and nerves to the internal ear and conveys the facial nerve to the stylomastoid foramen.

The Sphenoid (Figure 7-8)

General Functions: The **sphenoid** forms part of the floor of the cranium, unites the cranial and facial bones, and acts as a cross-brace that strengthens the sides of the skull. Mucus from the *sphenoidal sinuses* within this bone helps clean the surfaces of the nasal cavities.

Joints: The sphenoid articulates with the ethmoid and the frontal, occipital, parietal, and temporal bones of the cranium and the palatine bones, zygomatic bones, maxillae, and vomer of the face (**Figure 7-3c,d,e** and **Spotlight Figure 7-4**).

Regions/Markings (**Figure 7-8**): The shape of the sphenoid can be compared to a bat with its wings extended. This bone is relatively large, but more superficial bones hide much of it.

The **body** forms the central axis of the sphenoid.

The **sella turcica** (TUR-si-kuh; “Turkish saddle”) is a bony, saddle-shaped enclosure on the superior surface of the body (**Figure 7-8a**). Within the sella turcica is a depression known as the **hypophyseal** (hī-pō-FIZ-ē-al) **fossa** (**Spotlight Figure 7-4a**). This fossa contains the *pituitary gland*.

Figure 7-8 The Sphenoid.

The **sphenoidal sinuses** (Figure 7-8b) are on either side of the body, inferior to the sella turcica.

The **lesser wings** extend horizontally anterior to the sella turcica.

The **greater wings** extend laterally from the body and form part of the cranial floor. A sharp *sphenoidal spine* lies at the posterior, lateral corner of each greater wing. Anteriorly, each greater wing forms part of the posterior wall orbit.

The **pterygoid** (TER-i-goyd; *pterygion*, wing) **processes** are vertical projections that originate on either side of the body. Each pterygoid process forms a pair of *pterygoid plates*, which are attachment sites for muscles that move the mandible and soft palate.

Foramina (Spotlight Figure 7-4b and Figure 7-8): The **optic canals** permit passage of the optic nerves from the eyes to the brain. The **prechiasmatic sulcus**, also known as the *optic groove*, is a narrow groove anterior to the optic chiasm, the point where two optic nerves cross.

Penetrating each greater wing are a **superior orbital fissure**, **foramen rotundum**, **foramen ovale** (ō-VAH-lē), and **foramen spinosum**. These passages carry blood vessels and nerves to the orbit, face, jaws, and membranes of the cranial cavity, respectively.

The Ethmoid (Figure 7-9)

General Functions: The **ethmoid** forms the anteromedial floor of the cranium, the roof of the nasal cavity, and part of

the nasal septum (which subdivides the nasal cavity) and medial orbital wall. Mucus from a network of sinuses, or *ethmoidal cells*, within this bone flushes the surfaces of the nasal cavities.

Joints: The ethmoid articulates with the frontal bone and sphenoid of the cranium and with the maxillae, nasal, lacrimal, and palatine bones, and the inferior nasal conchae and vomer of the face (Figure 7-3c,d and Spotlight Figure 7-4).

Regions/Markings: The ethmoid has three parts: (1) the cribriform plate, (2) the ethmoidal labyrinth, and (3) the perpendicular plate (Figure 7-9a).

The **cribriform plate** (*cribrum*, sieve) forms the anteromedial floor of the cranium and the roof of the nasal cavity. The **crista galli** (*crista*, crest + *gallus*, rooster, cock; “cock’s comb”) is a bony ridge that projects superior to the cribriform plate. A membrane that stabilizes the position of the brain, the *falx cerebri*, attaches to this ridge.

An **ethmoidal labyrinth** opens into the nasal cavity on each side. Each labyrinth consists of **ethmoidal cells**, interconnected air-filled cavities. The cells are arranged in three groups, anterior, middle, and posterior, and are closed laterally by the orbital plate, which forms part of the wall of the orbit. The **superior nasal conchae** (KONG-kē; singular, *concha*; a snail shell) and the **middle nasal conchae** are delicate projections that form part of the ethmoidal labyrinth (Figure 7-9b).

The **perpendicular plate** forms part of the nasal septum, along with the vomer and a piece of hyaline cartilage.

Figure 7-9 The Ethmoid.

Foramina: The **olfactory foramina** in the cribriform plate permit passage of the olfactory nerves, which provide the sense of smell.

Remarks: *Olfactory* (smell) *receptors* are located in the epithelium that covers the inferior surfaces of the cribriform plate, the medial surfaces of the superior nasal conchae, and the superior portion of the perpendicular plate.

The nasal conchae break up the airflow in the nasal cavity. They create swirls, turbulence, and eddies that have three major effects: (1) Particles in the air are thrown against the sticky mucus that covers the walls of the nasal cavity; (2) air movement is slowed, providing time for warming, humidifying, and removing dust before the air reaches more delicate portions of the respiratory tract; and (3) air is directed toward the superior portion of the nasal cavity, adjacent to the cribriform plate, where the olfactory receptors are located.

Facial Bones

The Maxillae (Figure 7–10a,b)

General Functions: The paired **maxillae**, or *upper jawbones*, support the upper teeth and form the inferior orbital rims, the lateral margins of the external nares, the upper jaw, and most of the hard palate. The *maxillary sinuses* in these bones produce mucus that flushes the inferior surfaces of the nasal cavities. The maxillae are the largest facial bones, and the maxillary sinuses are the largest sinuses.

Joints: The maxillae articulate with the frontal bones and ethmoid, with one another, and with all the other facial bones except the mandible (Figure 7–3c,d,e and Spotlight Figure 7–4a).

Regions/Markings: The **orbital rim** protects the eye and other structures in the orbit (Figure 7–10a). The *anterior nasal spine* is found at the anterior portion of the maxilla, at its articulation

Figure 7–10 The Maxillae and Palatine Bones.

with the maxilla of the other side. It is an attachment point for the cartilaginous anterior portion of the nasal septum.

The **alveolar process** of the maxilla is a projecting ridge that contains the tooth sockets for the upper teeth.

The **palatine processes** form most of the **hard palate**, or bony roof of the mouth. A developmental disorder known as a *cleft palate* occurs when the maxillae fail to meet along the midline of the hard palate, resulting in a split in the roof of the mouth.

The **maxillary sinuses** lighten the portion of the maxillae superior to the teeth (**Figure 7-10b**).

The **nasolacrimal canal** is formed by a maxilla and a lacrimal bone. It protects the *lacrimal sac* and the **nasolacrimal duct**, which carries tears from the orbit to the nasal cavity.

Foramina: The **infra-orbital foramen** marks the path of a major sensory nerve that reaches the brain by the foramen rotundum of the sphenoid.

The **inferior orbital fissure** (**Figure 7-3d**) lies between the maxilla and the sphenoid. It permits passage of cranial nerves and blood vessels.

The Palatine Bones (**Figure 7-10b,c**)

General Functions: The paired **palatine bones** form the posterior portions of the hard palate. They also contribute to the floor of each orbit.

Joints: The palatine bones articulate with one another, with the maxillae, with the sphenoid and ethmoid, with the inferior nasal conchae, and with the vomer (**Figure 7-3e** and **Spotlight Figure 7-4a**).

Regions/Markings: The palatine bones are shaped like an L (**Figure 7-10c**). The **horizontal plate** forms the posterior part of the hard palate. The **perpendicular plate** extends from the horizontal plate to the **orbital process**, which forms part of the floor of the orbit. This process contains a small sinus that usually opens into the sphenoidal sinus.

Foramina: Small blood vessels and nerves supplying the roof of the mouth penetrate the lateral portion of the horizontal plate.

The Nasal Bones (**Figure 7-11**)

General Functions: The paired **nasal bones** support the superior portions of the bridge of the nose. They are connected to cartilages that support the distal portions of the nose. These flexible cartilages, and associated soft tissues, extend to the superior border of the **external nares** (NA-rēz; singular, *naris*), the entrances to the nasal cavity.

Joints: The paired nasal bones articulate with one another, with the ethmoid, and with the frontal bone and maxillae (**Figure 7-3b,c,d** and **Spotlight Figure 7-4a**).

Figure 7-11 The Smaller Bones of the Face.

The Vomer (Figure 7-11)

General Functions: The **vomer** forms the inferior portion of the bony nasal septum.

Joints: The vomer articulates with the maxillae, sphenoid, ethmoid, and palatine bones, and with the cartilaginous part of the nasal septum, which extends into the fleshy part of the nose (Figure 7-3d,e and Spotlight Figure 7-4a).

The Inferior Nasal Conchae (Figure 7-11)

General Functions: The paired **inferior nasal conchae** slow inhaled air and create turbulence as the air passes through the nasal cavity. They also increase the epithelial surface area to warm and humidify inhaled air.

Joints: The inferior nasal conchae articulate with the maxillae, ethmoid, palatine, and lacrimal bones (Figure 7-3d).

The Zygomatic Bones (Figure 7-11)

General Functions: The paired **zygomatic bones** contribute to the rims and lateral walls of the orbits and form the prominent cheekbones and parts of the zygomatic arches.

Joints: The zygomatic bones articulate with the maxillae, and the sphenoid, frontal, and temporal bones (Figure 7-3b,c,d,e).

Regions/Markings: The **temporal process** curves posteriorly to meet the zygomatic process of the temporal bone.

Foramina: The **zygomaticofacial foramen** on the anterior surface of each zygomatic bone carries a sensory nerve that innervates the cheek.

The Lacrimal Bones (Figure 7-11)

General Functions: The paired **lacrimal bones** form parts of the medial walls of the orbits.

Joints: The lacrimal bones are the smallest facial bones. They articulate with the frontal bone and maxillae, and with the ethmoid (Figure 7-3c,d).

Regions/Markings: The **lacrimal sulcus**, a groove along the anterior, lateral surface of the lacrimal bone, marks the location of the lacrimal sac. The lacrimal sulcus leads to the nasolacrimal canal, which begins at the orbit and opens into the nasal cavity. As noted earlier, the lacrimal bone and the maxilla form this canal.

The Mandible (Figure 7-12)

General Functions: The **mandible** forms the lower jaw.

Joints: The mandible articulates with the mandibular fossae of the temporal bones (Figures 7-3c,e and 7-7b).

Figure 7-12 The Mandible.

Regions/Markings: The **body** of the mandible is the horizontal portion of that bone (**Figure 7-12a**).

The **alveolar part** of the mandible is the portion of the mandible that surrounds and supports the lower teeth. The *dental alveoli* are the sockets for the roots of the teeth.

The *mental protuberance* (*mentalis*, chin) is the attachment site for several facial muscles.

The **ramus** of the mandible is the ascending part that begins at the *angle* of the mandible on either side.

On each ramus:

- The **condylar process** articulates with the temporal bone at the *temporomandibular joint*.
- The **coronoid** (KOR-ō-noyd) **process** is the insertion point for the *temporalis*, a powerful muscle that closes the jaws.
- The **mandibular notch** is the depression that separates the condylar and coronoid processes.

A prominent depression on the mandible's medial surface marks the position of the *submandibular salivary gland* (**Figure 7-12b**).

The *mylohyoid line* marks the insertion of the *mylohyoid*, which supports the floor of the mouth.

Foramina: The **mental foramina** are openings for nerves that carry sensory information from the lips and chin to the brain.

The **mandibular foramen** is the entrance to the *mandibular canal*, a passageway for blood vessels and nerves that service the lower teeth. Dentists typically anesthetize the sensory nerve that enters this canal before they work on the lower teeth.

The Hyoid Bone (Figure 7-13)

General Functions: The **hyoid bone** supports the larynx (voice box) and is the attachment site for muscles of the larynx, pharynx, and tongue.

Joints: *Stylohyoid ligaments* connect the *lesser horns* to the styloid processes of the temporal bones.

Regions/Processes: The **body** of the hyoid is an attachment site for muscles of the larynx, pharynx, and tongue.

The larger and more lateral **greater horns** help support the larynx and are attached to muscles that move the tongue.

The shorter and more medial **lesser horns** are attached to the stylohyoid ligaments. From these ligaments, the hyoid and larynx hang beneath the skull like a swing from the limb of a tree.

Figure 7-13 A Superior View of the Hyoid Bone.

Clinical Note Temporomandibular Joint Syndrome

The *temporomandibular joint* (TMJ) is a movable joint between each temporal bone and the mandible. This joint allows the jaw to move while chewing or talking. The disadvantage of such mobility is that forceful forward or lateral movement can dislocate the jaw. The connective tissue sheath, or *capsule*, that surrounds the joint is relatively loose. A pad of fibrocartilage separates the opposing bone surfaces. In **TMJ syndrome**, the mandible is pulled slightly out of alignment, generally by spasms in one of the jaw muscles. The person has facial pain that radiates around the ear on the affected side and cannot open the mouth fully. TMJ syndrome is a repeating cycle of muscle spasm → misalignment → pain → muscle spasm. It has been linked to involuntary behaviors, such as grinding the teeth during sleep (*bruxism*) and to emotional stress. Treatment focuses on breaking the cycle of muscle spasm and pain. Applying heat to the affected joint, and using anti-inflammatory medications, local anesthetics, or both, may help. If teeth grinding is suspected, special mouth guards may be worn during sleep.

Sinuses, Foramina, and Fissures

Sinuses, foramina, and fissures are bone markings that describe openings in bones. Several bones of the skull contain air-filled chambers called **sinuses**. Sinuses are identified in the sagittal section of the cranial cavity in **Spotlight Figure 7-4a**. Sinuses have three major functions: (1) They lessen the weight of the bone; (2) they are lined with mucous membranes, which produce mucus that moistens and cleans the air in and near the sinus; and (3) they are resonating chambers in speech production. We considered the sinuses as we discussed specific bones (**Figures 7-5 to 7-12**). **Figure 7-3d,e** and **Spotlight Figure 7-4b** show important foramina and fissures in cranial and facial bones, along with the major structures using these passageways.

✓ Checkpoint

3. In which bone is the foramen magnum located?
4. Tomás is hit in the head with a baseball that fractures the right superior lateral surface of his cranium. Which bone is fractured?
5. Which bone contains the depression called the sella turcica? What is found in this depression?
6. Identify the facial bones.
7. Identify the bone containing the mental foramen and list the structures using this passageway.
8. Identify the bone containing the optic canal and cite the structures using this passageway.
9. Name the foramina found in the ethmoid bone.

See the blue Answers tab at the back of the book.

7-3 Each orbital complex contains and protects an eye, and the nasal complex encloses the nasal cavities

Learning Outcome Describe the structure and functions of the orbital complex, nasal complex, and paranasal sinuses.

The facial bones not only protect and support the openings of the digestive and respiratory systems, but also protect the sense organs responsible for vision and smell. Together, certain cranial bones and facial bones form an *orbital complex*, which surrounds each eye, and the *nasal complex*, which surrounds the nasal cavities.

The Orbital Complexes

The **orbits** are the bony sockets that contain and protect the eyes. Seven bones of the **orbital complex** form each orbit (**Figure 7-14**). The frontal bone (1) forms the roof, and the maxilla (2) provides most of the orbital floor. The orbital rim and the first portion of the medial wall are formed by the maxilla, the lacrimal bone (3), and the ethmoidal labyrinth of the ethmoid (4). The ethmoidal labyrinth articulates with the sphenoid (5) and a small process of the palatine bone (6). Several prominent foramina and fissures penetrate the sphenoid or lie between it and the maxilla. The *superior orbital fissure* is a cleft through which nerves controlling eye movement pass. Laterally, the sphenoid and maxilla articulate with the zygomatic bone (7), which forms the lateral wall and rim of the orbit.

Figure 7-14 The Orbital Complex. The right orbital region.

Figure 7–15 The Nasal Complex.

a A sagittal section through the skull, with the nasal septum removed to show major features of the wall of the right nasal cavity. The frontal and sphenoidal sinuses are visible.

b Locations of the paranasal sinuses.

The Nasal Complex

The **nasal complex** (Figure 7–15) includes the bones that enclose the nasal cavities and the *paranasal sinuses*, air-filled chambers connected to the nasal cavities. The frontal bone, sphenoid, and ethmoid form the superior wall of the nasal cavities (Figure 7–15a). The lateral walls are formed by the maxillae and the lacrimal bones (not shown), the ethmoid (the superior and middle nasal conchae), and the inferior nasal conchae. The soft tissues of the nose form much of the anterior margin of the nasal cavity, but the maxillae and nasal bones support the bridge of the nose.

The sphenoid, ethmoid, frontal bone, and paired palatine bones and maxillae contain the **paranasal sinuses**. Figure 7–15b shows the locations of the *frontal* and *sphenoidal sinuses*, *ethmoidal cells*, and *maxillary sinuses*. (The tiny palatine sinuses, not shown, generally open into the sphenoidal sinuses.) The paranasal sinuses lighten the skull bones and house an extensive area of mucous epithelium, which releases mucus into the nasal cavities. This ciliated epithelium moves the mucus back toward the throat, where it is eventually swallowed or expelled by coughing. Incoming air is humidified and warmed as it flows across this thick carpet of mucus. Foreign particulates, such as dust or microorganisms, become trapped in the sticky mucus and are then swallowed or expelled. This mechanism helps protect the more delicate portions of the respiratory tract.

Checkpoint

10. Identify the bones of the orbital complex.
11. Identify the bones of the nasal complex.
12. Identify the bones containing the paranasal sinuses.

See the blue Answers tab at the back of the book.

7-4 Fontanelles are non-ossified fibrous areas between cranial bones that ease birth and allow for rapid brain growth in infants and children

Learning Outcome Describe the key structural differences among the skulls of infants, children, and adults.

Many different centers of ossification are involved in forming the skull. As development proceeds, the centers fuse, producing a smaller number of composite bones. For example, the sphenoid begins as 14 separate ossification centers.

The skull organizes around the developing brain. As the time of birth approaches, the brain enlarges rapidly. The bones of the skull are also growing, but they fail to keep pace. At birth, fusion is not yet complete: There are two frontal bones, four occipital bones, and several sphenoid and temporal elements. At this time, the cranial bones are connected by areas of fibrous connective tissue (Figure 7–16). The connections are quite flexible, so the skull can withstand the distortion that normally takes place during delivery.

Clinical Note Sinusitis

When an irritant or allergen, such as pepper, pollen, or dust, is introduced into the nasal passages, our bodies work to remove it, often by sneezing. The sneeze expels the irritant out with the air. Small particles or milder irritants may trigger mucus production by the epithelium of the paranasal sinuses. The mucus stream flushes the nasal surfaces, often removing the irritants. In *allergic rhinitis* (rĭ-Nĭ-tus), an overactive immune response to an allergen causes excessive mucosal swelling, mucus production, and sneezing.

A sinus infection is another matter entirely. A viral, bacterial, or fungal infection produces an inflammation of the mucous membrane of the nasal cavity. As the membrane swells, the small passageways called *ostia* within the paranasal sinuses narrow. Mucus drains more slowly, the sinuses fill, and the person experiences headaches and pressure within the facial bones. This condition is called **sinusitis**. The maxillary sinuses are commonly involved.

Sinusitis pain relief is the basis of a large over-the-counter drug market in the United States. The active ingredients in these drugs dry the epithelial linings, reduce pain, and restrict further swelling. A nondrug remedy is the *neti* (NEH-tē) pot. To use this small teapot-shaped vessel, it is filled with warm salt water and gently poured into the nostrils while the head is tilted over the sink. The salt water flows through the nasal cavity, irrigating the nasal passages, and out the other nostril. The process is repeated on the other side.

Chronic (long-term) sinusitis may accompany chronic allergies. It may also occur as the result of a **deviated nasal septum**, in which the cartilaginous structure dividing the nasal is bent. Septal deviation often blocks the drainage of one or more sinuses, producing chronic cycles of infection and inflammation. A deviated septum can result from injuries to the nose and can usually be corrected or improved by surgery.

7

The largest fibrous areas between the cranial bones are known as **fontanelles** (fon-tuh-NELZ; sometimes spelled *fontanels*). There are six such fontanelles:

- The paired *sphenoidal fontanelles* are at the junctions between the squamous sutures and the coronal suture (**Figure 7-16a**).
- The paired *mastoid fontanelles* are at the junctions between the squamous sutures and the lambdoid suture.
- The *anterior fontanelle* is the largest fontanelle. It lies at the intersection of the frontal, sagittal, and coronal sutures in the anterior portion of the skull (**Figure 7-16b**).
- The *posterior fontanelle* is at the junction between the lambdoid and sagittal sutures.

The anterior fontanelle is often called the “soft spot” on newborns. It is usually the only fontanelle easily seen and felt. The anterior fontanelle pulses as the heart beats because it covers a major blood vessel. This fontanelle is sometimes used to determine whether an infant is dehydrated, because the surface becomes indented when blood volume is low.

The sphenoidal, mastoid, and posterior fontanelles disappear within a month or two after birth. The anterior fontanelle generally persists until the child is nearly 2 years old. Even after the fontanelles disappear, the bones of the skull remain separated by fibrous connections.

The skulls of infants and adults differ in other ways as well, such as in the shape and structure of cranial elements. This difference accounts for variations in proportions as well as in size. The cranium of a young child, compared with the skull as a whole, is relatively larger than that of an adult. The most significant growth in the skull takes place before age 5, because at that age the brain stops enlarging and the cranial sutures develop. The growth of the cranium is generally coordinated with the expansion of the brain. If one or more sutures form before the brain stops growing, the skull will be abnormal in shape, size, or both.

Checkpoint

13. Define fontanelle and identify the major fontanelles.
14. What purpose does a fontanelle serve?

See the blue Answers tab at the back of the book.

Figure 7-16 Infant Skull and Fontanelles.

Name the fontanelles found on the infant skull. Why aren't they labeled on the adult skull?

Clinical Note Craniostenosis

Malformations of the skull can result from *craniostenosis* (krā-nē-ō-sten-ō-sis; *stenosis*, narrowing), the premature closure of cranial fontanelles. As the brain continues to enlarge, the rest of the skull changes shape to accommodate it. A long and narrow head is produced by early closure of the sagittal suture. A very broad skull results if the coronal suture forms prematurely. Early closure of all cranial sutures restricts the development of the brain, and surgery must be performed to prevent brain damage. If brain enlargement stops due to genetic or developmental abnormalities, however, skull growth ceases as well. This condition, which results in an undersized head, is called *microcephaly* (mī-krō-SEF-uh-lē; *micro-*, small + *cephalon*, head).

the **coccyx** (KOK-siks), or tailbone (1). The vertebrae provide a column of support, bearing the weight of the head, neck, and trunk, and ultimately transferring the weight to the appendicular skeleton of the lower limbs. The vertebrae also protect the spinal cord and help maintain an upright body position, as when we sit or stand. The average length of the vertebral column of an adult male and female is about 71 cm (28 in.) and 61 cm (24 in.), respectively.

The vertebral column is not straight and rigid. A lateral view shows four **spinal curves**: (1) the **cervical curve**, (2) the **thoracic curve**, (3) the **lumbar curve**, and (4) the **sacral curve** (Figure 7-17).

The central line of an infant's body, called the axis, forms a C shape, with the back curving posteriorly. The C shape results from the thoracic and sacral curves. These are called **primary curves** because they appear in fetal development. They are also called *accommodation curves* because they accommodate the thoracic and abdominopelvic viscera (internal organs). The primary curves are present at birth.

The cervical and lumbar curves, known as **secondary curves**, appear several months after birth. They are also called *compensation curves*, because they help shift the weight to permit an upright posture. The cervical and lumbar secondary curves become accentuated as the toddler learns to walk and run. All four curves are fully developed by age 10.

When standing, the body weight must be transmitted through the vertebral column to the hips and ultimately to the lower limbs. Yet most body weight lies anterior to the vertebral column. The various curves bring that weight in line with the body axis. Think about what someone may automatically do when standing with a heavy object hugged to their chest. They avoid toppling forward by exaggerating their lumbar curve and by keeping their weight back toward the body axis. This posture can lead to discomfort at the base of the spinal

7-5 The vertebral column has four flexible and supportive spinal curves

Learning Outcome Identify and describe the curves of the spinal column and indicate the function of each.

The rest of the axial skeleton consists of the vertebral column, ribs, and sternum. The adult **vertebral column**, or *spine*, consists of 26 bones: the **vertebrae** (24), the **sacrum** (1), and

column. For example, in the last 3 months of pregnancy, many females develop chronic back pain from the changes in lumbar curvature that adjust for the increasing weight of the fetus. In many parts of the world, people often carry heavy objects balanced on their head. This practice increases the load on the vertebral column but does not affect the spinal curves because the weight is aligned with the axis of the spine.

✓ Checkpoint

15. What is the importance of the secondary curves of the spine?
16. List the components of the vertebral column.

See the blue Answers tab at the back of the book.

7-6 The five vertebral regions—cervical, thoracic, lumbar, sacral, and coccygeal—each have characteristic vertebrae

Learning Outcome Identify the five vertebral regions and describe the distinctive structural and functional characteristics of the vertebrae in each region.

As **Figure 7-17** shows, the vertebral column is divided into *cervical*, *thoracic*, *lumbar*, *sacral*, and *coccygeal* regions. The cervical, thoracic, and lumbar regions consist of individual vertebrae. Seven **cervical vertebrae** (designated C₁–C₇ or CI–CVII) make up the neck and extend inferiorly to the trunk. Twelve **thoracic vertebrae** (T₁–T₁₂ or TI–TXII) form the superior portion of the back. Each articulates with one or more pairs of ribs. Five **lumbar vertebrae** (L₁–L₅ or LI–LV) form the inferior portion of the back. The fifth articulates with the sacrum, which in turn articulates with the coccyx.

We now look first at the general characteristics of vertebra, and then at the differences among vertebrae in each of these regions.

Vertebral Anatomy

Each vertebra consists of three basic parts: (1) a *vertebral body*, (2) a *vertebral arch*, and (3) *articular processes* (**Figure 7-18a**). Most vertebrae also have several types of processes that do not articulate with other bones.

The **vertebral body** is the part of a vertebra that transfers weight along the axis of the vertebral column. The body forms

Figure 7-17 The Vertebral Column.

Which two regions of the spine form primary curves?

the anterior margin of each **vertebral foramen**, while the **vertebral arch** forms the posterior margin (**Figure 7-18a,b**). The vertebral arch has walls, called **pedicles** (PED-i-kulz), and a roof, formed by flat layers called **laminae** (LAM-i-nē; singular, *lamina*, a thin plate) (**Figure 7-18a**). The pedicles arise along the posterior and lateral margins of the body. The laminae on either side extend dorsally and medially to complete the roof.

A **spinous process** projects posteriorly from the point where the vertebral laminae fuse to complete the vertebral arch (**Figure 7-18b,c**). A person can see—and feel—the spinous processes through the skin of the back when the spine is flexed. **Transverse processes** project laterally or dorsolaterally on both sides from the point where the laminae join the pedicles. These processes are sites of muscle attachment, and they may also articulate with the ribs.

Figure 7–18 Vertebral Anatomy.

Like the transverse processes, the **articular processes** arise at the junction between the pedicles and the laminae (**Figure 7–18c,d**). A **superior** and an **inferior articular process** lie on each side of the vertebra. The superior articular processes articulate with the inferior articular processes of a more superior vertebra (or the occipital condyles, in the case of the first cervical vertebra). The inferior articular processes articulate with the superior articular processes of a more inferior vertebra (or the sacrum, in the case of the last lumbar vertebra). Each articular process has a smooth concave surface called an **articular facet**. The superior processes have articular facets on their dorsal surfaces, whereas the inferior processes articulate along their ventral surfaces.

The bodies of adjacent vertebrae are interconnected by ligaments, but are separated by pads of fibrocartilage, the **intervertebral discs**. Gaps called **intervertebral foramina** separate the pedicles of successive vertebrae. These gaps permit the passage of nerves running to or from the enclosed spinal cord. Together, the vertebral foramina of successive vertebrae form the **vertebral canal**, which encloses the spinal cord (**Figure 7–18e**).

Characteristics of Regional Vertebrae

Each vertebra has characteristic markings and articulations. Here we focus on the general characteristics of each region. Note that when we refer to a specific vertebra, we use a capital

Figure 7-19 The Cervical Vertebrae.

letter to indicate its vertebral region: C, T, L, S, and Co represent the cervical, thoracic, lumbar, sacral, and coccygeal regions, respectively. In addition, we use a numerical subscript to indicate the relative position of the vertebra within that region, with 1 indicating the vertebra closest to the skull. For example, C₁ is in contact with the skull, and C₃ is the third cervical vertebra. Similarly, T₁₂ is in contact with L₁, and L₄ is the fourth lumbar vertebra (Figure 7-17). We will use this shorthand throughout the text.

Keep in mind that the diameter of the spinal cord decreases as you proceed caudally along the vertebral canal, and so does the diameter of the vertebral arch. As you continue toward the sacrum, the loading increases and the vertebral bodies gradually enlarge. Next, we describe how regional variations reflect each vertebral group's function.

Cervical Vertebrae

Most mammals—whether giraffes, whales, mice, or humans—have seven cervical vertebrae, C₁ to C₇ (Figure 7-19a). The cervical vertebrae extend from the occipital bone of the skull to the thorax. These vertebrae are the smallest in the vertebral column. In addition, the body of a cervical vertebra is small compared with the size of its vertebral foramen (Figure 7-19b). Because cervical vertebrae support only the weight of the head, the vertebral body is relatively small and light.

Laterally, the **transverse process** of cervical vertebrae C₃, C₄, C₅, and C₆ are fused to the **anterior tubercle** and **posterior tubercle**. Together, they encircle the **transverse foramen** (Figure 7-19b). The transverse foramina are passageways for vertebral arteries and vertebral veins, which are important blood vessels serving the brain.

In a typical cervical vertebra, the superior surface of the body is concave from side to side, and it slopes, with the anterior edge inferior to the posterior edge (**Figure 7-19c**). Vertebra C_1 has no spinous process. The spinous processes of the other cervical vertebrae are relatively stumpy, generally shorter than the diameter of the vertebral foramen. In the case of vertebrae C_2 – C_6 , the tip of each spinous process has a prominent notch (**Figure 7-19b**). A split spinous process is said to be **bifid** (BĪ-fid).

The preceding description is adequate for identifying the cervical vertebrae C_3 – C_6 . The first two cervical vertebrae are quite unique, and the seventh is a modified version of the C_3 – C_6 vertebrae (we describe these vertebrae shortly). The interlocking bodies of articulated C_3 – C_7 permit more flexibility than do those of other regions.

Compared with the cervical vertebrae, the head is relatively massive. It sits atop the cervical vertebrae like a soup bowl on the tip of a finger. With this arrangement, small muscles can produce significant effects by tipping the balance one way or another. But if one's position changes suddenly, as in a fall or during rapid acceleration (a jet takeoff) or deceleration (a car crash), the balancing muscles are not strong enough to stabilize the head. A dangerous partial or complete dislocation of the cervical vertebrae can result, with injury to muscles and ligaments and potential injury to the spinal cord. We use the term **whiplash** to describe such an injury, because the movement of the head resembles the cracking of a whip.

The Atlas (C_1). The **atlas**, cervical vertebra C_1 , holds up the head and articulates with the occipital condyles of the skull (**Figure 7-19d**). The joint between the occipital condyles and the atlas is a joint that permits nodding, such as occurs when indicating “yes.” The atlas can easily be distinguished from other vertebrae by (1) the lack of a body and spinous process and (2) the presence of a large, round vertebral foramen bounded by **anterior** and **posterior arches**.

The Axis (C_2). During development, the body of the atlas fuses to the body of the second cervical vertebra, called the **axis** (C_2) (**Figure 7-19d**). This fusion creates the prominent **dens** (DENZ; *dens*, tooth), or *odontoid* (ō-DON-toyd; *odoous*, tooth) *process*, of the axis. A transverse ligament binds the dens to the inner surface of the atlas, forming a pivot for rotation of the atlas and skull. Important muscles controlling the position of the head and neck attach to the prominent spinous process of the axis. The atlas-axis articulation permits rotation, as when a person shakes their head to indicate “no.”

In children, the fusion between the dens and axis is incomplete. Impacts or even severe shaking can cause dislocation of the dens and severe damage to the spinal cord. In adults, a hit to the base of the skull can be equally dangerous, because a dislocation of the atlas-axis joint can force the dens into the base of the brain, with fatal results.

The Vertebra Prominens (C_7). The transition from one vertebral region to another is not abrupt. The last vertebra of one region generally resembles the first vertebra of the next. The **vertebra prominens** (prominent vertebra), or seventh cervical vertebra (C_7), has a long, slender spinous process (**Figure 7-19a**) that ends in a broad tubercle that can be felt through the skin at the base of the neck. This vertebra is the interface between the cervical curve, which arches anteriorly, and the thoracic curve, which arches posteriorly (**Figure 7-17a**). The transverse processes of C_7 are large, providing additional surface area for muscle attachment.

The **ligamentum nuchae** (lig-uh-MEN-tum NŪ-kē; *nucha*, nape), a strong elastic ligament, begins at the vertebra prominens and extends to an insertion (attachment site) along the external occipital crest of the skull. Along the way, it attaches to the spinous processes of the other cervical vertebrae. When the head is upright, this ligament acts like the string on a bow, maintaining the cervical curvature without muscular effort. If the neck bends forward, the elasticity in the ligamentum nuchae helps return the head to an upright position.

Thoracic Vertebrae

There are 12 thoracic vertebrae, T_1 to T_{12} (**Figure 7-20a**). A typical thoracic vertebra has a distinctive heart-shaped body that is more massive than that of a cervical vertebra (**Figure 7-20b**). The vertebral foramen is smaller in relation to the vertebral body than in the cervical vertebrae. The long, slender spinous process projects posteriorly and inferiorly.

Each thoracic vertebra articulates with ribs along the dorsolateral surfaces of the body. The **costal facets** on the vertebral bodies articulate with the heads of the ribs. The location and structure of the joints vary somewhat among thoracic vertebrae (**Figure 7-20a**). Vertebrae T_1 – T_8 each articulate with two pairs of ribs, so their vertebral bodies have two costal facets (*superior* and *inferior*) on each side. Vertebrae T_9 – T_{11} have a single costal facet on each side, and each vertebra articulates with a single pair of ribs. The transverse processes of vertebrae T_1 – T_{10} are relatively thick and contain **transverse costal facets** for rib articulation (**Figure 7-20b,c**). Thus, rib pairs 1 through 10 contact their vertebrae at two points: a costal facet and a transverse costal facet.

The spinous processes of T_{10} , T_{11} , and T_{12} increasingly resemble those of the lumbar region as the transition between the thoracic and lumbar curves approaches. Because the inferior thoracic and lumbar vertebrae carry so much weight, the transition between the thoracic and lumbar curves is difficult to stabilize. As a result, compression fracture dislocations from a hard fall tend to involve the last thoracic vertebra and first two lumbar vertebrae.

Figure 7-20 The Thoracic Vertebrae.

Lumbar Vertebrae

The five lumbar vertebrae (L₁–L₅) are the largest vertebrae (**Figure 7-21a**). The body of a typical lumbar vertebra (**Figure 7-21b,c**) is thicker than that of a thoracic vertebra, and the superior and inferior surfaces are oval rather than heart shaped. Also note that lumbar vertebrae do not have costal facets or transverse costal facets. The slender transverse processes project dorsolaterally, while the stumpy spinous processes project dorsally. The vertebral foramen is triangular. Finally, the superior articular processes face medially (“up and in”), and the inferior articular processes face laterally (“down and out”).

The lumbar vertebrae withstand the most weight. Their massive spinous processes provide surface area for the attachment of lower back muscles that reinforce or adjust the lumbar curve.

Table 7-1 summarizes the features of cervical, thoracic, and lumbar vertebrae.

Tips

To remember the number of bones in the first three spinal curves, think about mealtimes. Breakfast is at 7 a.m. (7 cervical vertebrae), lunch at 12 p.m. (12 thoracic vertebrae), and dinner at 5 p.m. (5 lumbar vertebrae).

The Sacrum

The sacrum consists of the fused components of five sacral vertebrae. These vertebrae begin fusing shortly after puberty and are generally completely fused at ages 25–30. The sacrum

Figure 7–21 The Lumbar Vertebrae.

protects the reproductive, digestive, and urinary organs. Through paired joints, it attaches the axial skeleton to the paired hip bones, or pelvic girdle, of the appendicular skeleton (**Figure 7–1a**).

The superior articular processes of the first sacral vertebra articulate with the last lumbar vertebra, L₅. The **sacral canal** is a passageway that begins between these articular processes and extends the length of the sacrum (**Figure 7–22a**). Nerves and membranes that line the vertebral canal in the spinal cord continue into the sacral canal.

The broad, posterior sacral surface has an extensive area for muscle attachment, especially for muscles that move the thigh. Three sacral crests, the *median* and *lateral sacral crests*, and the *sacral cornu*, provide these attachment sites (**Figure 7–22b**). The **median sacral crest** is a ridge formed by the fused spinous processes of the sacral vertebrae. The laminae of the fifth sacral vertebra fail to contact one another at the midline. They form the **sacral cornua** (KOR-nū-uh; singular, *cornu*; *cornua*, horns). These ridges form the margins

of the **sacral hiatus** (hī-Ā-tus), the opening at the inferior end of the sacral canal. This opening is covered by connective tissues. Four pairs of **sacral foramina** open on either side of the median sacral crest. The intervertebral foramina of the fused sacral vertebrae open into these passageways. Each **lateral sacral crest** is a ridge that represents the fused transverse processes of the sacral vertebrae.

The sacrum is curved, with a convex posterior surface (**Figure 7–22b**). The degree of curvature is more pronounced in males than in females. The **auricular surface** is a thickened, flattened area lateral and anterior to the superior part of the lateral sacral crest. The auricular surface is the site of articulation with the pelvic girdle (the *sacro-iliac joint*). The **sacral tuberosity** (**Figure 7–22a**) is a roughened area between the lateral sacral crest and the auricular surface. It marks the attachment site of ligaments that stabilize the sacro-iliac joint.

The subdivisions of the sacrum are most obvious in anterior view (**Figure 7–22c**). The narrow, inferior portion

Table 7-1 Regional Differences in Vertebral Structure and Function

Feature	Type (Number)		
	Cervical Vertebrae (7)	Thoracic Vertebrae (12)	Lumbar Vertebrae (5)
Location	Neck	Chest	Inferior portion of back
Body	Small, oval, curved faces	Medium, heart-shaped, flat faces; facets for rib articulations	Massive, oval, flat faces
Vertebral foramen	Large	Medium	Small
Spinous process	Long; split tip; points inferiorly	Long, slender; not split; points inferiorly	Blunt, broad; points posteriorly
Transverse processes	Have transverse foramina	All but two (T ₁₁ , T ₁₂) have facets for rib joints	Short; no articular facets or transverse foramina
Functions	Support skull, stabilize relative positions of brain and spinal cord, and allow controlled head movement	Support weight of head, neck, upper limbs, and chest; articulate with ribs to allow changes in volume of thoracic cage	Support weight of head, neck, upper limbs, and trunk

Typical appearance (superior view)

Figure 7-22 The Sacrum and Coccyx.

+ Clinical Note Kyphosis, Lordosis, and Scoliosis

The vertebral column must move, balance, and support the trunk and head. Conditions that damage the bones, muscles, and/or nerves can result in distorted curves and impaired function. **Kyphosis** (kī-FŌ-sis; *kyphos*, hump-backed) is an excessive posterior curvature of the thoracic vertebral column, producing a “round-back” appearance (**Photo a**). This condition can be caused by (1) osteoporosis with compression fractures affecting the anterior portions of vertebral bodies, (2) chronic contractions in muscles that insert on the vertebrae, or (3) abnormal vertebral growth. In **lordosis** (lor-DŌ-sis; *lordosis*, bent backwards), or “sway-back,” both the abdomen and buttocks protrude excessively (**Photo b**). This causes an anterior exaggeration of the lumbar curvature. This may occur during pregnancy or

result from abdominal obesity or abdominal wall muscle weakness. **Scoliosis** (skō-lē-Ō-sis; *scoliosis*, crookedness) is an excessive lateral curvature of the spine in one or more of the movable vertebrae (**Photo c**). This condition may result from damage to vertebral bodies during development, or from muscular paralysis affecting one side of the back (as in some cases of polio). In many cases, the cause of excessive spinal curvatures is not known. Idiopathic (of no known cause) scoliosis generally appears in females during adolescence, when growth is most rapid. Small curves may later stabilize once growth is complete. For larger curves, bracing may prevent progression. Severe cases can be treated through surgical straightening with implanted metal rods or cables.

a Kyphosis

b Lordosis

c Scoliosis

is the sacral **apex**. The broad superior surface is the **base**. The **sacral promontory**, a prominent bulge at the anterior tip of the base, is an important landmark in females during pelvic examinations and during labor and delivery. Prominent *transverse lines* mark the former boundaries of individual vertebrae that fuse during the formation of the sacrum. At the base of the sacrum, a broad sacral **ala**, or *wing*, extends on either side. The anterior and superior surfaces of each ala provide an extensive area for muscle attachment. At the apex, a flattened area marks the site of articulation with the coccyx.

The Coccyx

The small coccyx consists of four (in some cases three or five) coccygeal vertebrae (**Figure 7-22**). Ossification of the distal coccygeal vertebrae is not complete before puberty. These vertebrae generally begin fusing by age 26, and fusion takes place thereafter at a variable pace. The coccygeal vertebrae do not fuse completely until late in adulthood. In very old persons, the coccyx may fuse with the sacrum.

Ligaments and a muscle that constricts the anal opening are attached to the coccyx. The first two coccygeal vertebrae have transverse processes and unfused vertebral arches. The

prominent lamina of the first coccygeal vertebrae is known as the **coccygeal cornu**. Each lamina curves to meet the sacral cornu.

17. Why does the vertebral column of an adult have fewer vertebrae than that of a newborn?
18. Joe has a hairline fracture (fracture without separation of the fragments) at the base of the dens. Which bone is fractured, and where is it located?
19. Examining a human vertebra, your lab partner notices that, in addition to the large foramen for the spinal cord, two smaller foramina are on either side of the bone in the region of the transverse processes. From which region of the vertebral column is this vertebra?
20. Why are the bodies of the lumbar vertebrae larger than those of the cervical and thoracic vertebrae?

See the blue Answers tab at the back of the book.

7-7 The thoracic cage protects organs in the chest and provides sites for muscle attachment

Learning Outcome Explain the significance of the joints between the thoracic vertebrae and ribs, and between the ribs and sternum.

The skeleton of the chest, or **thoracic cage** (Figure 7-23), provides bony support to the walls of the thoracic cavity. It consists of the thoracic vertebrae, the ribs, costal cartilages, and the sternum (breastbone). The thoracic cage as a whole serves the following main functions:

- It protects the heart, lungs, thymus, and other structures in the thoracic cavity.
- It serves as an attachment point for muscles involved in (1) breathing, (2) maintaining the position of the vertebral column, and (3) moving the pectoral girdles (both clavicles and scapulae) and upper limbs.

7

Figure 7-23 The Thoracic Cage.

Which two pairs of ribs are the floating ribs? What distinguishes them from the other false ribs?

The ribs and the sternum form the *rib cage*, whose movements are important in breathing. Let's look at the components of the rib cage more closely.

The Ribs

Ribs are long, curved, flattened bones that originate on or between the thoracic vertebrae and end in the wall of the thoracic cavity. Each of us usually has 12 pairs of ribs (**Figure 7-23a**). The first seven pairs (ribs 1–7; I–VII) are called **true ribs**, or *vertebrosternal ribs*. They reach the anterior body wall and are connected to the sternum by separate cartilaginous extensions, the **costal cartilages**. Beginning with the upper first rib, the vertebrosteral ribs gradually increase in length and in radius of curvature.

Ribs 8–12 (VIII–XII) are called **false ribs** because they do not attach directly to the sternum. The costal cartilages of ribs 8–10, the *vertebrochondral ribs*, fuse together and merge with the cartilages of rib pair 7 before they reach the sternum. The last two pairs of ribs (11–12; XI–XII) are called *floating ribs* because they have no connection with the sternum. They are also called *vertebral ribs* because they are attached only to the vertebrae (**Figure 7-23b**) and muscles of the body wall.

Figure 7-24a shows the superior surface of a typical rib. The *vertebral end* of the rib articulates with the vertebral column at the **head**, or *capitulum* (ka-PIT-ū-lum). A ridge divides the articular surface of the head into superior and inferior articular facets (**Figure 7-24b**). From the head, a short **neck** leads to the **tubercle**, a small elevation that projects dorsally. The inferior portion of the tubercle contains an articular facet that contacts the transverse process of the thoracic vertebra.

The bend, or *angle*, of the rib is the site where the tubular **body**, or *shaft*, begins curving toward the sternum (**Figure 7-24b**). The internal rib surface is concave, and a prominent *costal groove* along its inferior border marks the path of nerves and blood vessels. The superficial surface is convex and provides an attachment site for muscles of the pectoral girdle and trunk. The *intercostal muscles*, which move the ribs, are attached to the superior and inferior surfaces.

Ribs 1 and 10 originate at costal facets on vertebrae T₁ and T₁₀, respectively, and their tubercular facets articulate with the transverse costal facets on those vertebrae. The heads of ribs 2–9 articulate with costal facets on two adjacent vertebrae. Their tubercular facets articulate with the transverse costal facets of the inferior member of the vertebral pair. Ribs 11 and 12, which originate at T₁₁ and T₁₂, do not have tubercular facets and do not contact the transverse processes of T₁₁ or T₁₂.

The ribs are quite mobile, due to their complex musculature, dual articulations at the vertebrae, and flexible connection to the sternum. Note how the ribs angle inferiorly as they

Figure 7-24 The Ribs.

curve away from the vertebral column (**Figure 7-23b**). Because of their curvature, the movements of the ribs during breathing change the position of the sternum. Lowering the ribs pulls the sternum inward, and raising the ribs moves it outward. As a result, movements of the ribs change both the width and the depth of the thoracic cage, decreasing or increasing its volume accordingly as we breathe out or in. These movements are important in breathing, as we detail in Chapter 23.

The ribs can bend and move to cushion shocks and absorb hits, but severe or sudden impacts can cause painful rib fractures. A cracked rib can heal without a cast or splint because the ribs are tightly bound in connective tissues. But comminuted fractures of the ribs can send bone splinters or fragments into the thoracic cavity, with potential damage to internal organs.

Surgery on the heart, lungs, or other organs in the thorax typically involves entering the thoracic cavity. The mobility of the ribs and the cartilaginous connections with the sternum allow the ribs to be temporarily moved out of the way. “Rib spreaders” are used to push the ribs apart in much the same way that a jack lifts a car off the ground for a tire change. If more extensive access is required, the cartilages of the sternum can be cut and the entire sternum folded out of the way. Once the sternum is replaced, scar tissue reunites the cartilages, and the ribs heal fairly rapidly.

The Sternum

The adult **sternum**, or breastbone, is a flat bone that forms in the anterior midline of the thoracic wall (**Figure 7-23a**). The sternum has the following three parts:

- The broad, triangular **manubrium** (ma-NŪ-brē-um) articulates with the *clavicles* (collarbones) and the cartilages of the first pair of ribs. The manubrium is the widest and most superior portion of the sternum. Only the first pair of ribs is attached by cartilage to this portion of the sternum. The **jugular notch**, located between the clavicular articulations, is a shallow indentation on the superior surface of the manubrium.
- The tongue-shaped **body** attaches to the inferior surface of the manubrium and extends inferiorly along the midline. Individual costal cartilages from rib pairs 2–7 attach to this portion of the sternum.
- The **xiphoid** (ZI-foyd) **process** is the smallest part of the sternum. It is attached to the inferior surface of the body. The *diaphragm* (breathing muscle) and *rectus abdominis* muscle attach to the xiphoid process.

Ossification of the sternum begins at 6 to 10 ossification centers, and fusion is not complete until at least age 25. Before that age, the sternal body consists of four separate bones. In adults, their boundaries appear as a series of transverse lines crossing the sternum. The xiphoid process is generally the last part to ossify and fuse. Its connection to the sternal body can be broken by impact or strong pressure, creating a spear of bone that can severely damage the liver. The xiphoid process is used as a palpable landmark during the administration of cardiopulmonary resuscitation (CPR), and CPR training strongly emphasizes proper hand positioning to reduce the chances of breaking ribs or the xiphoid process.

Checkpoint

21. Describe false ribs.
22. Improper administration of cardiopulmonary resuscitation (CPR) can result in a fracture of which bones?
23. What are the main differences between true ribs and floating ribs?

See the blue Answers tab at the back of the book.

7 Chapter Review

Study Outline

An Introduction to the Divisions of the Skeleton

1. The human skeleton has two main divisions: the **axial skeleton** and the **appendicular skeleton**. The axial skeleton forms the longitudinal axis of the body, and the appendicular skeleton includes the pectoral and pelvic girdles, which support the limbs. (*Figure 7-1*)

7-1 The 80 bones of the head and trunk make up the axial skeleton

2. The **axial skeleton** is divided into the **skull** and **associated bones** (**auditory ossicles** and **hyoid**), the **thoracic cage**, and the **vertebral column**. (*Figures 7-1, 7-3*)

7-2 The skull's 8 cranial bones protect the brain, and its 14 facial bones form the mouth, nose, and orbits

3. The **skull** consists of the **cranium** and the bones of the face. The cranium, composed of **cranial bones**, encloses the **cranial cavity**. The **facial bones** protect and support the entrances to the digestive and respiratory tracts. (*Figures 7-2, 7-3*)
4. Prominent superficial landmarks on the skull include the **lambdoid**, **coronal**, **sagittal**, and **squamous sutures**. (*Figure 7-3, Spotlight Figure 7-4*)

Media Resources:

- Chapter Quizzes, Chapter Practice Test, MP3 Tutor Sessions, and Clinical Case Studies

- PhysioEx

5. The bones of the cranium are the **occipital bone**, the two **parietal bones**, the **frontal bone**, the two **temporal bones**, the **sphenoid**, and the **ethmoid**. (*Figures 7-2 to 7-9*)
6. The occipital bone surrounds the **foramen magnum**. (*Figures 7-3 to 7-5*)
7. The frontal bone contains the **frontal sinuses**. (*Spotlight Figure 7-4, Figure 7-6*)
8. The **auditory ossicles** are located in a cavity within the temporal bone. (*Figure 7-7*)
9. The bones of the face are the **maxillae**, the **palatine bones**, the **nasal bones**, the **vomer**, the **inferior nasal conchae**, the **zygomatic bones**, the **lacrimal bones**, and the **mandible**. (*Figures 7-2 to Spotlight Figure 7-4, 7-10 to 7-12*)

10. The left and right maxillae, or **maxillary bones**, are the largest facial bones; they form the upper jaw and most of the **hard palate**. (Figures 7–3, Spotlight Figure 7–4, 7–10)
11. The palatine bones are small L-shaped bones that form the posterior portions of the hard palate and contribute to the floor of the orbital cavities. (Figures 7–3, Spotlight Figure 7–4, 7–10)
12. The paired nasal bones extend to the superior border of the **external nares**. (Figures 7–3, Spotlight Figure 7–4, 7–11)
13. The vomer forms the inferior portion of the **nasal septum**. (Figures 7–3, Spotlight Figure 7–4, 7–11)
14. The **temporal process** of the zygomatic bone articulates with the **zygomatic process** of the temporal bone to form the **zygomatic arch**. (Figures 7–3, 7–7, 7–11)
15. The paired lacrimal bones, the smallest bones of the face, are situated medially in each **orbit**. (Figures 7–3, 7–11)
16. The mandible is the bone of the lower jaw. (Figures 7–3, Spotlight Figure 7–4, 7–12)
17. The **hyoid bone**, suspended by **stylohyoid ligaments**, supports the larynx. (Figure 7–13)
18. The foramina and fissures of the adult skull are summarized in Spotlight Figure 7–4.

7-3 Each orbital complex contains and protects an eye, and the nasal complex encloses the nasal cavities

19. Seven bones form each **orbital complex**. (Figure 7–14)
20. The **nasal complex** includes the bones that enclose the nasal cavities and the **paranasal sinuses**, hollow airways that connect with the nasal passages. (Figure 7–15)

7-4 Fontanelles are non-ossified fibrous areas between cranial bones that ease birth and allow for rapid brain growth in infants and children

21. Fibrous connective tissue **fontanelles** permit the skulls of infants and children to continue growing after birth. (Figure 7–16)

7-5 The vertebral column has four flexible and supportive spinal curves

22. The **vertebral column** consists of the vertebrae, sacrum, and coccyx. We have 7 **cervical vertebrae** (the first articulates with the skull), 12 **thoracic vertebrae** (which articulate with the ribs), and 5 **lumbar vertebrae** (the last articulates with the sacrum). The **sacrum** and **coccyx** consist of fused vertebrae. (Figure 7–17)

23. The spinal column has four **spinal curves**. The **thoracic** and **sacral curves** are called **primary** or **accommodation curves**; the **lumbar** and **cervical curves** are known as **secondary** or **compensation curves**. (Figure 7–17)
24. A typical vertebra has a **vertebral body** and a **vertebral arch** and articulates with adjacent vertebrae at the **superior** and **inferior articular processes**. (Figure 7–18)
25. **Intervertebral discs** separate adjacent vertebrae. Spaces between successive **pedicles** form the **intervertebral foramina**. (Figure 7–18)

7-6 The five vertebral regions—cervical, thoracic, lumbar, sacral, and coccygeal—each have characteristic vertebrae

26. Cervical vertebrae are distinguished by the shape of the body, the relative size of the vertebral foramen, the presence of **anterior** and **posterior tubercles** with **transverse foramina**, and notched **spinous processes**. These vertebrae include the **atlas**, **axis**, and **vertebra prominens**. (Figure 7–19; Table 7–1)
27. Thoracic vertebrae have a distinctive heart-shaped body; long, slender spinous processes; and articulations for the ribs. (Figures 7–20, 7–23; Table 7–1)
28. The lumbar vertebrae are the most massive and least mobile of the vertebrae; they are subjected to the greatest strains. (Figure 7–21; Table 7–1)
29. The sacrum protects reproductive, digestive, and urinary organs and articulates with the pelvic girdle and with the fused elements of the coccyx. (Figure 7–22)

7-7 The thoracic cage protects organs in the chest and provides sites for muscle attachment

30. The skeleton of the **thoracic cage** consists of the thoracic vertebrae, the ribs, and the sternum. The **ribs** and **sternum** form the **rib cage**. (Figure 7–23)
31. Ribs 1–7 are **true ribs**, or **vertebrosternal ribs**. Ribs 8–12 are called **false ribs**; they include the **vertebrochondral ribs** (ribs 8–10) and two pairs of **floating (vertebral) ribs** (ribs 11–12). A typical rib has a **head**, or **capitulum**; a **neck**; a **tubercle**; an **angle**; and a **body**, or **shaft**. A **costal groove** marks the path of nerves and blood vessels. (Figures 7–23, 7–24)
32. The sternum consists of the **manubrium**, **body**, and **xiphoid process**. (Figure 7–23)

Review Questions

See the blue Answers tab at the back of the book.

LEVEL 1 Reviewing Facts and Terms

1. Identify the cranial and facial bones in the diagram below.

Cranial bones

Facial bones

2. Which of the following lists contains *only* facial bones? (a) mandible, maxilla, nasal, zygomatic, (b) frontal, occipital, zygomatic, parietal, (c) occipital, sphenoid, temporal, lacrimal, (d) frontal, parietal, occipital, sphenoid.
3. The unpaired facial bones include the (a) lacrimal and nasal, (b) vomer and mandible, (c) maxilla and mandible, (d) zygomatic and palatine.
4. All of the following are parts of the ethmoid, *except* the (a) crista galli, (b) perpendicular plate, (c) pterygoid process, (d) cribriform plate.
5. The zygomatic process is a part of the (a) zygomatic bone, (b) temporal bone, (c) maxilla, (d) mandible.
6. Blood vessels that drain blood from the head pass through the (a) jugular foramina, (b) hypoglossal canals, (c) stylomastoid foramina, (d) mental foramina, (e) lateral canals.
7. For each of the following vertebrae, indicate its vertebral region.

- (a) _____ (b) _____ (c) _____

8. Lumbar vertebrae can be distinguished from other vertebrae by the presence of (a) a massive vertebral body, (b) the transverse foramina, (c) a bifid spinous process, (d) transverse costal facets, (e) an anterior arch.
9. The bony ridge you can feel through the skin of your back is formed by the (a) pedicles, (b) spinous processes, (c) intervertebral discs, (d) transverse processes, (e) laminae.
10. The part of the vertebra that transfers weight along the axis of the vertebral column is the (a) vertebral arch, (b) lamina, (c) pedicles, (d) body.
11. List the eight bones of the skull that come in pairs.
12. What seven bones make up the orbital complex?
13. Which bones make up the hard palate?
14. In addition to the spinal curves, what skeletal element contributes to the flexibility of the vertebral column?

LEVEL 2 Reviewing Concepts

15. What is the relationship among the lacrimal bones, the maxillae, and the nasal cavity?
16. What is the relationship between the nasal conchae and other skull bones?
17. Describe how rib movement functions in breathing.
18. Why is it important to keep the back straight when lifting a heavy object?
19. The axis (C_2) can be distinguished from the other vertebrae by the presence of (a) the transverse foramina, (b) an anterior vertebral arch, (c) the dens, (d) superior and inferior articular facets.
20. What is the function of the paranasal sinuses?
21. The secondary spinal curves (a) help position the body weight over the legs, (b) accommodate the thoracic and abdominopelvic viscera, (c) include the thoracic curvature, (d) do all of these, (e) do only a and c.
22. When you nod your head to express approval, (a) the atlas and the axis act together, (b) the atlas rotates on the occipital condyles, (c) the atlas rotates on the dens of the axis, (d) all cervical vertebrae rotate, (e) the inferior cervical vertebra rotates on the superior thoracic vertebra.
23. The _____ is/are the attachment site for the muscles of the tongue. (a) body of the mandible, (b) paired palatine processes of the maxilla, (c) atlas, (d) hyoid, (e) dens axis.

LEVEL 3 Critical Thinking and Clinical Applications

24. Jane has an upper respiratory infection and begins to feel pain in her teeth. This is a good indication that the infection is located in the (a) frontal sinuses, (b) sphenoid, (c) temporal bone, (d) maxillary sinuses, (e) zygomatic bones.
25. While working at an excavation, an archaeologist finds several small skull bones. She examines the frontal, parietal, and occipital bones and concludes that the skulls are those of children not yet 1 year old. How can she tell their ages from an examination of these bones?
26. When Helen's baby was born, the doctor noticed some abnormality in the form and circumference of the skull. Radiography and a CT scan confirmed craniostenosis. Explain what craniostenosis is and how it develops.

CLINICAL CASE Wrap-Up Knocked Out

The young boxer has sustained a “blowout” fracture of his left orbital complex. The orbit that contains the eye is formed by seven facial bones and is surrounded by four air-filled sinuses. The orbital rim is strong, composed of thick, protective bone. But the very thin medial wall and floor of the orbit were literally blown out by the intact eyeball itself when he was struck with such a forceful punch.

A computerized tomography (CT) scan reveals fractures of the ethmoid, lacrimal, palatine, and maxillary bones that make up the delicate medial wall and floor of the left orbit. Many tiny fracture fragments are visible within the maxillary sinus.

The opening to the air-filled sinus allowed the air to escape into the soft tissues surrounding the eye when the fighter coughed,

causing the subcutaneous air expansion around the eye. The muscles that move the eye had become entrapped within the fracture fragments, preventing the fighter from gazing upward and giving rise to his double vision.

The young boxer is taken to the operating room. A surgical repair of the orbital floor is performed, using an implant to support the eyeball until fracture healing is complete.

1. What are the seven bones that make up each orbital complex?
2. What are the four paranasal sinuses surrounding each orbital complex?

See the blue Answers tab at the back of the book.

Related Clinical Terms

craniotomy: The surgical removal of a section of bone (bone flap) from the skull for the purpose of operating on the underlying tissues.

deviated nasal septum: A bent nasal septum (cartilaginous structure dividing the left and right nasal cavities) that slows or prevents sinus drainage.

herniated disc: A disc (fibrocartilage pad) between the vertebrae that slips out of place or ruptures; if it presses on a nerve, it can cause back pain or sciatica.

laminectomy: A surgical operation to remove the posterior vertebral arch on a vertebra, usually to give access to the spinal cord or to relieve pressure on nerves.

spina bifida: A condition resulting from the failure of the vertebral laminae to unite during development; commonly associated with developmental abnormalities of the brain and spinal cord.

spinal fusion: A surgical procedure that stabilizes the spine by joining together (fusing) two or more vertebrae using bone grafts, metal rods, or screws.

8

The Appendicular Skeleton

Learning Outcomes

These Learning Outcomes correspond by number to this chapter's sections and indicate what you should be able to do after completing the chapter.

- 8-1 ■ Identify the bones that form the pectoral girdles, their functions, and their surface features.
- 8-2 ■ Identify the bones of the upper limbs, their functions, and their surface features.
- 8-3 ■ Identify the bones that form the pelvic girdle, their functions, and their surface features.
- 8-4 ■ Identify the bones of the lower limbs, their functions, and their surface features.
- 8-5 ■ Summarize sex differences and age-related changes in the human skeleton.

CLINICAL CASE

Head Over Heals

“Let’s race!” said Sipho as he cycled home from school with his friend, Xolani. Sipho started peddling furiously and was soon racing ahead but, as he turned back to see where Xolani was, the front wheel of his bicycle hit a pothole and Sipho flew over the handlebars. To try and break his fall, Sipho put his right arm out but landed hard on his arm and shoulder. Xolani soon caught up to him and tried to help him stand but when he did, Sipho cried out as pain shot across his upper chest.

“I’ll go and fetch help” said Xolani, and he set off for the village and twenty minutes later, returned with Sipho’s mother.

“What happened, Sipho?” she said. “Let’s get you to the clinic immediately.”

When they arrived, the doctor noticed that Sipho was holding his right arm and his right shoulder was sagging. He also had an inflamed, raised area near his sternum. She had a good idea of Sipho’s injury, but an x-ray taken later confirmed her suspicions. **What was Sipho’s injury? To find out, turn to the Clinical Case Wrap-Up at the end of the chapter.**

8

An Introduction to the Appendicular Skeleton

In the previous chapter, we discussed the 80 bones of the axial skeleton that protect and support internal organs. In this chapter we focus on the remaining bones of the skeletal system, which are appended (attached) to the axial skeleton. The **appendicular skeleton** includes the bones of the limbs and the supporting bone girdles that connect the limbs to the trunk (**Figure 8-1**).

Muscles attached to the axial skeleton take part in vital functions, such as breathing. When considering the role of the appendicular skeleton, think about the actions of arms, hands, legs, and feet. Skeletal muscles attach to bones of the appendicular skeleton to permit gross movement, such as walking, or fine movement, such as texting.

The appendicular skeleton is dominated by the long bones that form the limbs. The upper limbs enable free movement, and the lower limbs are adapted for movement and support. Long bones share common features. For example, one epiphysis is usually called the *head*, the diaphysis is called the *shaft*, and the narrower metaphysis between the head and shaft is called the *neck*.

8-1 The pectoral (shoulder) girdles attach the upper limbs to the axial skeleton

Learning Outcome Identify the bones that form the pectoral girdles, their functions, and their surface features.

Each arm *articulates* (that is, forms a joint) with the trunk at a **pectoral girdle**, or *shoulder girdle* (**Figures 8-1, 8-2a**). The pectoral girdles consist of four bones—two S-shaped *clavicles* (KLAV-i-kulz; collarbones) and two broad, flat *scapulae* (SKAP-ū-lē; singular, *scapula*, SKAP-ū-luh; shoulder blades).

The medial, anterior end of each clavicle articulates with the manubrium of the sternum. These joints are the *only* direct connections between the pectoral girdles and the axial skeleton. Skeletal muscles support and position the scapulae, which have no direct bony or ligamentous connections to the thoracic cage. As a result, the shoulders are extremely mobile, but not very strong.

Movements of the clavicles and scapulae position the shoulder joints and provide a basis for arm movement. The shoulder joints are positioned and stabilized by skeletal muscles that extend between the axial skeleton and the pectoral girdles. Once the joints are in position, other skeletal muscles, including several that originate on the pectoral girdle, move the upper limbs.

The surfaces of the scapulae and clavicles are important sites for muscle attachment. Bony ridges and projections mark the attachment sites of major muscles. Other bone markings, such as sulci or foramina, indicate the positions of nerves that control the muscles or the passage of blood vessels that nourish the muscles and bones. Note that in the descriptions of bones in this chapter, we emphasize surface markings that either have functional importance (such as the attachment sites for skeletal muscles and the paths of major nerves and blood vessels) or are anatomical landmarks (such as the xiphoid process for administering cardiopulmonary resuscitation).

The Clavicles

The paired **clavicles** are S-shaped bones that originate at the superior, lateral border of the manubrium of the sternum, lateral to the jugular notch (**Figure 8-2a**). From this pyramid-shaped **sternal end**, each clavicle curves laterally and posteriorly for about half its length. It then forms a smooth posterior curve to articulate with a process of the scapula, the *acromion* (a-KRŌ-mē-on). The flat, **acromial end** of the clavicle is broader than the sternal end (**Figure 8-2b,c**).

Figure 8–1 An Anterior View of the Appendicular Skeleton. The numbers in the boxes indicate the total number of bones of each type or within each category.

What structures comprise the appendicular skeleton?

Figure 8-2 The Right Clavicle.**a** The position of the clavicle within the pectoral girdle, anterior view**b** Superior view of the right clavicle**c** Inferior view of the right clavicle

The smooth, superior surface of the clavicle lies just beneath the skin. The acromial end has a rough inferior surface that has prominent lines and tubercles (**Figure 8-2c**). The *conoid tubercle* and *costal tuberosity* on the inferior surface are attachment sites for muscles and ligaments of the shoulder. The combination of the direction of curvature and the differences between superior and inferior surfaces makes it easy to distinguish a left clavicle from a right clavicle.

A person can explore the connection between their own clavicles and sternum. If they use their fingers and press their jugular notch (the depression just superior to the manubrium), they locate the clavicle on each side and find the *sternoclavicular joints* where the sternum articulates with the clavicles. When they move their shoulders, they can feel the sternal ends of the clavicles change their positions.

The clavicles are small and fragile, so it's no surprise that fractures of the clavicle are common. For example, a simple fall can fracture a clavicle if a person landed on their hand with their arm outstretched. Fortunately, most clavicular fractures heal rapidly with a simple clavicle strap.

The Scapulae

The paired **scapulae** are flat bones found on the posterior side of the rib cage. Each triangular-shaped scapula is made up of two large processes for muscular attachment and the *glenoid cavity* for articulation with the humerus (**Figure 8-3**). The three sides of each scapula are the **superior border**; the **medial border**, or *vertebral border*; and the **lateral border**

(**Figure 8-3a,c**), or *axillary border*. Muscles that position the scapula attach along these sides. The corners of the triangle are called the *superior angle*, the *inferior angle*, and the *lateral angle*. The anterior, or *costal*, surface of the scapula is smooth and concave. The depression in the anterior surface is called the **subscapular fossa**.

The lateral angle of the scapula forms a broad process that supports the cup-shaped **glenoid cavity** (**Figure 8-3a,b**). At the glenoid cavity, the scapula articulates with the *humerus*, the proximal bone of the upper limb. This articulation is the shoulder joint, also known as the *glenohumeral joint*.

Two large scapular processes extend beyond the margin of the glenoid cavity (**Figure 8-3b**) superior to the head of the humerus. The smaller, anterior projection is the **coracoid** (KOR-uh-koyd) **process**. The **acromion** is the larger, posterior process. If someone runs their fingers along the superior surface of their shoulder joint, they will feel this process. The acromion articulates with the clavicle at the *acromioclavicular joint*. Ligaments and tendons associated with the shoulder joint are attached to both the coracoid process and the acromion.

The acromion is continuous with the **spine** of the scapula, a ridge that crosses the posterior surface before ending at the medial border (**Figure 8-3c**). The scapular spine divides the convex posterior surface into two regions. The area superior to this spine is the **supraspinous fossa** (*supra*, above). The region inferior to the spine is the **infraspinous fossa** (*infra*, beneath). Small ridges and lines mark the entire posterior surface where smaller muscles attach to the scapula.

Figure 8-3 The Right Scapula.

✓ Checkpoint

1. Name the bones of the pectoral girdles.
2. How would a broken clavicle affect the mobility of the scapula?
3. Which bone articulates with the scapula at the glenoid cavity?

See the blue Answers tab at the back of the book.

8-2 The bones of the upper limbs are adapted for free movement

Learning Outcome Identify the bones of the upper limbs, their functions, and their surface features.

The skeleton of the upper limbs consists of the bones of the arms, forearms, wrists, and hands. Note that in anatomical descriptions, the term *arm* refers only to the proximal portion of the upper limb (from shoulder to elbow), not to the entire limb. The distal portion of the upper limb (from elbow to wrist) is the *forearm*. Let's examine the bones of the right upper limb.

The Humerus

The arm, or *brachium*, contains only one long bone, the **humerus**, which extends from the scapula to the elbow. From proximal to distal, the main parts of the humerus are the *head*, *shaft*, and *condyle*, where it articulates with the forearm bones.

At the proximal end of the humerus, the round **head** articulates with the scapula (**Figure 8-4a,b**). The prominent **greater tubercle** is a rounded projection on the lateral surface of the epiphysis, near the margin of the humeral head. The greater tubercle establishes the lateral contour of the shoulder. The position can be verified by feeling for a bump located a few centimeters from the tip of the acromion. The **lesser tubercle** is a smaller projection that lies on the anterior, medial surface of the epiphysis, separated from the greater tubercle by the **intertubercular sulcus**, or *bicipital groove*. A large tendon runs along the groove. Both tubercles are important sites for muscle attachment.

The **anatomical neck** lies between the tubercles and the articular surface of the head. This neck marks the extent of the joint capsule. The narrower distal **surgical neck** corresponds to the metaphysis of the growing bone. The name reflects the fact that fractures typically occur at this site.

The proximal shaft of the humerus is round in section. The **deltoid tuberosity** is a large, rough elevation on the lateral surface of the shaft, approximately halfway along its length. It is named after the *deltoid*, a muscle that attaches to it.

On the posterior surface, the deltoid tuberosity ends at the **radial groove** (**Figure 8-4b**). This depression marks the path of the *radial nerve*, a large nerve for both sensory information from the posterior surface of the limb and motor control over the

Figure 8-4 The Right Humerus and Elbow Joint. Note that for simplicity, an illustration of a single bone throughout this chapter has labels that do not include the name of the bone. For example, these photographs of a humerus have the label *Head* rather than *Head of the humerus*, or *Humeral head*. In figures where more than one bone is shown, labels use complete names to avoid confusion.

large muscles that straighten (extend) the elbow. Distal to the radial groove, the posterior surface of the humerus is almost flat.

Near the distal articulation with the bones of the forearm, the humeral shaft expands to either side at the **medial** and **lateral epicondyles**. *Epicondyles* are processes that develop proximal to an articulation. They provide additional surface

area for muscle attachment. The prominent medial head and the differences between the medial and lateral epicondyles make it easy to tell a left humerus from a right humerus.

The *ulnar nerve* crosses the posterior surface of the medial epicondyle. A hit at the posteromedial surface of the elbow joint can strike this nerve and produce a temporary numbness and paralysis

of muscles on the anterior surface of the forearm. Because of the odd sensation, this area is sometimes called the *funny bone*.

At the **condyle**, the humerus articulates with the *ulna* and the *radius*, the bones of the forearm. The condyle is divided into two articular regions: the trochlea and the capitulum (**Figure 8-4a,b**). The **trochlea** is the spool-shaped medial portion of the condyle. It extends from the base of the **coronoid fossa** on the anterior surface to the **olecranon** (ō-LEK-ruh-non) **fossa** on the posterior surface. The rounded **capitulum** forms the lateral surface of the condyle (**Figure 8-4c**).

A shallow **radial fossa** superior to the capitulum accommodates a portion of the radial head when the elbow bends (**Figure 8-4a**). Projections from the ulnar surface fit into the coronoid fossa (when bending the elbow) and the olecranon fossa (when straightening the elbow) as the elbow nears its total range of motion (**Figure 8-4d**).

Bones of the Forearm

The *ulna* and *radius* are parallel long bones that support the forearm, or *antebrachium*. In the anatomical position, the ulna lies medial to the radius. The **interosseous membrane**, a fibrous sheet, connects the lateral margin of the ulna to the radius (**Figure 8-5a,b**).

The Ulna

From proximal to distal, the **ulna** is made up of the **olecranon**, the shaft, and the **ulnar head**. The **olecranon**, the proximal end of the ulna, is the point of the elbow (**Figure 8-5a**). On the anterior surface of the proximal epiphysis, the **trochlear notch** of the ulna (**Figure 8-5b**) articulates with the trochlea of the humerus at the elbow joint. **Figure 8-5c** shows the trochlear notch of the ulna in a lateral view.

Figure 8-5 The Right Radius and Ulna.

Tips

The memory tool for olecranon involves the lowercase letter **l**: The knob felt at the elbow is the **olecranon** of the **ulna**. You can remember that the trochlear notch is a feature of the **ulna** because this notch forms a U in lateral view.

8

The olecranon forms the superior lip of the trochlear notch. The **coronoid process** forms its inferior lip. At the limit of *extension*, movement that straightens the forearm and arm, the olecranon swings into the olecranon fossa on the posterior surface of the humerus (**Figure 8-4d**). At the limit of *flexion*, a movement that decreases the angle between the articulating bones, the arm and forearm form a tight V, and the coronoid process projects into the coronoid fossa on the anterior humeral surface. Lateral to the coronoid process, a smooth **radial notch** accommodates the head of the radius at the *proximal radio-ulnar joint* (**Figure 8-5a**).

Viewed in cross section, the shaft of the ulna is triangular. Near the wrist, the shaft of the ulna narrows before ending at a disc-shaped **head of ulna**, or *ulnar head*. The posterior, lateral surface of the ulnar head has a short **ulnar styloid process** (*stylos*, pillar). A triangular cartilage, the *articular disc*, attaches to the styloid process. This cartilage separates the ulnar head from the bones of the wrist. The lateral surface of the ulnar head articulates with the distal end of the radius to form the *distal radio-ulnar joint* (**Figure 8-5b**).

The Radius

The **radius**, the lateral bone of the forearm, is made up of three main parts from proximal to distal: the *head of radius*, *shaft*, and *radial styloid process* (**Figure 8-5a**). The disc-shaped **head of radius** articulates with the capitulum of the humerus (**Figure 8-4c**). During flexion, the radial head swings into the radial fossa of the humerus. A narrow neck extends from the radial head to the **radial tuberosity** (**Figure 8-5b**). This tuberosity marks the attachment site of the *biceps brachii*, a large muscle on the anterior surface of the arm.

The shaft of the radius curves along its length. It also enlarges, and the distal portion of the radius is considerably larger than the distal portion of the ulna. The **ulnar notch** on the medial surface of the distal end of the radius marks the site of articulation with the head of the ulna (**Figure 8-5a**). An isolated radius or ulna can be quickly identified as left or right by finding the radial notch of the ulna or the ulnar notch of the radius and remembering that the radius lies lateral to the ulna.

The distal end of the radius articulates with the bones of the wrist. The **radial styloid process** on the lateral surface of the radius helps stabilize this joint (**Figure 8-5a,b**).

Bones of the Wrist and Hand

The *wrist*, or *carpus*, contains eight *carpal bones*. Some of the carpal bones articulate with the five *metacarpal* (met-uh-KAR-pul; *metacarpus*, hand) *bones* to support the hand (**Figure 8-6**). Each hand has 14 finger bones, or *phalanges* (fa-LAN-jēz; singular, *phalanx*, FĀ-lanks).

The Carpal (Wrist) Bones

The **carpal bones** in the wrist form two rows, one with four **proximal carpal bones** and the other with four **distal carpal bones**.

The proximal carpal bones are the scaphoid, lunate, triquetrum, and pisiform (**Figure 8-6**):

- The **scaphoid** (*skaphe*, boat) is the proximal carpal bone on the lateral border of the wrist. It is the carpal bone closest to the styloid process of the radius.
- The comma-shaped **lunate** (*luna*, moon) lies medial to the scaphoid. Like the scaphoid, it articulates with the radius.
- The **triquetrum** (trī-KWĒ-trum; *triquetrus*, three-cornered) is a small, pyramid-shaped bone medial to the lunate. The triquetrum articulates with the articular disc that separates the ulnar head from the wrist.
- The small, pea-shaped **pisiform** (PIS-i-form; *pisum*, pea) sits anterior to the triquetrum.

The distal carpal bones are the trapezium, trapezoid, capitate, and hamate (**Figure 8-6**):

- The **trapezium** (*trapezion*, four-sided with no parallel sides) is the lateral bone of the distal row. Its proximal surface articulates with the scaphoid.
- The wedge-shaped **trapezoid** lies medial to the trapezium. Like the trapezium, it has a proximal articulation with the scaphoid.
- The **capitate** (*caput*, head) is the largest carpal bone. It sits between the trapezoid and the hamate.
- The **hamate** (*hamatum*, hooked) is the medial distal carpal bone.

Tips

It may help to identify the eight carpal bones by remembering the sentence “Sam Likes To Push The Toy Car Hard.” In lateral to medial order, the first four words stand for the proximal carpal bones (scaphoid, lunate, triquetrum, pisiform). The last four stand for the distal carpal bones (trapezium, trapezoid, capitate, hamate).

The Metacarpals (Palm) and Phalanges (Fingers)

The five **metacarpals** of the hand are identified by Roman numerals I–V, beginning with the lateral metacarpal, which articulates with the trapezium (**Figure 8-6**). For example,

Figure 8–6 Bones of the Right Wrist and Hand.

With which carpal bones does metacarpal IV articulate?

Clinical Note Carpal Tunnel Syndrome

The carpal bones articulate with one another at joints that permit limited sliding and twisting. Ligaments interconnect the carpal bones and help stabilize the wrist joint. The tendons of muscles that flex the fingers pass across the anterior surface of the wrist. These tendons are sandwiched between the intercarpal ligaments and a broad, superficial transverse ligament called the *flexor retinaculum*. Inflammation of the connective tissues between the flexor retinaculum and the carpal bones can compress the tendons and the adjacent *median nerve*. The result is pain, weakness, and reduced wrist mobility. This condition, called *carpal tunnel syndrome*, is common in occupations that require repetitive wrist motion.

metacarpal I articulates with the proximal bone of the thumb.

Distally, the metacarpals articulate with the proximal **phalanges**, the finger bones. The first finger, known as the **pollex** (POL-eks), or thumb, has two phalanges (*proximal* and *distal*). Each of the other four fingers has three phalanges (*proximal*, *middle*, and *distal*).

✓ Checkpoint

4. List all the bones of an upper limb.
5. The rounded projections on either side of the elbow are parts of which bone?
6. Using the terms *lateral* and *medial*, describe the relationship between the forearm bones when a person is in the anatomical position.
7. Ricardo accidentally fractures his first distal phalanx with a hammer. Which finger is broken?

See the blue Answers tab at the back of the book.

8-3 The pelvic girdle (hips) attaches the lower limbs to the axial skeleton

Learning Outcome Identify the bones that form the pelvic girdle, their functions, and their surface features.

The bones of the pelvic girdle attach to the lower limbs (**Figure 8-1**) and must withstand the stresses involved in weight bearing and mobility. For this reason, they are more massive than the bones of the pectoral girdles.

In this section we first consider the *pelvic girdle*, which consists of the two *hip bones*. Then we examine the *pelvis*, a composite structure that includes the pelvic girdle of the appendicular skeleton plus the sacrum and coccyx of the axial skeleton.

The Pelvic Girdle (Hip Bones)

The **pelvic girdle** is made up of the paired **hip bones**, also called the **coxal bones**, or **pelvic bones**. Each hip bone forms by the fusion of three bones: an **ilium** (IL-ē-um; plural, *ilia*), an **ischium** (IS-kē-um; plural, *ischia*), and a **pubis** (PŪ-bis) (**Figure 8-7**).

On the lateral surface of each hip bone is an **acetabulum** (as-e-TAB-ŭ-lum; *acetabulum*, shallow vinegar cup), a concave socket that articulates with the head of the femur (**Figure 8-7a**). A ridge of bone forms the lateral and superior margins of the acetabulum, which has a diameter of about 5 cm (2 in.). The anterior and inferior portion of the ridge is incomplete, leaving a gap called the **acetabular notch**. The smooth, cup-shaped articular surface of the acetabulum is the **lunate surface**.

The ilium, ischium, and pubis meet inside the acetabulum, as though it were a pie sliced into three pieces. Superior to the acetabulum, the ilium forms a broad, curved surface that provides an extensive area for the attachment of muscles,

tendons, and ligaments (**Figure 8-7a**). Bone markings along the margin of the ilium include the *iliac spines*, which mark the attachment sites of important muscles and ligaments; the *gluteal lines*, which mark the attachment of large hip muscles; and the **greater sciatic** (sĭ-AT-ik) **notch**, through which a major nerve (the *sciatic nerve*) reaches the lower limb.

The broadest part of the ilium extends between the **arcuate line**, which is continuous with the pectineal line, and the **iliac crest** (**Figure 8-7b**). These prominent ridges mark the attachments of ligaments and muscles. The area between the arcuate line and the iliac crest forms a shallow depression known as the **iliac fossa**. The concave surface of the iliac fossa helps to support the abdominal organs. It also provides additional area for muscle attachment.

The ischium forms the posterior, inferior portion of the acetabulum. Posterior to the acetabulum, the prominent **ischial spine** projects superior to the *lesser sciatic notch*. Blood vessels, nerves, and a small muscle pass through this notch. The **ischial tuberosity**, a roughened projection, is located at the posterior and lateral edge of the ischium. When sitting, the ischial tuberosities support the body's weight.

The narrow **ischial ramus** continues until it meets the **inferior pubic ramus**. The inferior pubic ramus extends between the ischial ramus and the *pubic tubercle*, a small, elevated area anterior and lateral to the pubic symphysis. There the inferior pubic ramus meets the **superior pubic ramus**, which originates near the acetabulum. The *pectineal line*, a ridge that ends at the pubic tubercle, is found on the anterior, superior surface of the superior ramus (**Figure 8-7b**).

The pubic ramus and ischial ramus encircle the **obturator** (OB-tŭ-rā-tor) **foramen** (**Figure 8-7a**). This space is closed by a sheet of collagen fibers whose inner and outer surfaces provide a firm base for the attachment of muscles of the hip.

In a medial view of a hip bone, the anterior and medial surface of the pubis has a roughened area that marks the site of articulation with the pubis of the opposite side (**Figure 8-7b**). At this articulation—the **pubic symphysis**—the two pubic bones are attached to a middle pad of fibrocartilage.

The Pelvis (Pelvic Girdle, Sacrum, and Coccyx)

Figure 8-8 shows anterior and posterior views of the **pelvis**, which consists of the two hip bones, the sacrum, and the coccyx. Posteriorly, the **auricular surfaces** of the ilia have a sturdy articulation with the auricular surfaces of the sacrum, attaching the pelvic girdle to the axial skeleton at the *sacroiliac joints*. Ligaments arising at the **iliac tuberosity** (**Figure 8-7**), a roughened area superior to the auricular surface, stabilize this joint. An extensive network of ligaments connects the lateral borders of the sacrum with the iliac crest, the ischial tuberosity, the ischial spine, and the arcuate line. Other ligaments tie the

Figure 8-7 The Right Hip Bone. The left and right hip bones make up the pelvic girdle.

ilia to the posterior lumbar vertebrae. These interconnections increase the stability of the pelvis.

The pelvic cavity is the space enclosed by the bones of the pelvis. The pelvis may be divided into the *true (lesser) pelvis* and the *false (greater) pelvis* that is separated by the pelvic brim (**Figure 8-9a,b**). The **true pelvis** is inferior to the pelvic brim. The superior limit of the true pelvis is a line that extends from either side of the base of the sacrum, along the arcuate line and pectineal line to the pubic symphysis. The bony edge of the true pelvis is called the **pelvic brim**, or *linea terminalis*. The enclosed space is the **pelvic inlet**. The **false pelvis** is the upper portion of the pelvic cavity surrounded by the broad, bladelike portions of each ilium superior to the pelvic brim (**Figure 8-9a**).

The **pelvic outlet** is the opening bounded by the coccyx, the ischial tuberosities, and the inferior border of the pubic symphysis (**Figure 8-9b,c**). The surface region bordered by the inferior edges of the pelvis is called the *perineum* (per-i-NĒ-um). Perineal muscles form the floor of the pelvic cavity and support the organs in the true pelvis.

The shape of the pelvis of a female is somewhat different from that of a male. Some of the differences are the result of variations in body size and muscle mass. For example, in females, the pelvis is generally smoother and lighter and has less-prominent markings. Look ahead to **Spotlight Figure 8-14** for a comparison of some major overall differences between adult male and female pelvises.

Figure 8–8 The Pelvis of an Adult Male. (Return to Figure 7–22 for a detailed view of the sacrum and coccyx.)

What is the correct term for the opening formed by the pubis and the ischium?

Checkpoint

8. Name the bones of the pelvic girdle.
9. Which three bones make up a hip bone?
10. When seated, which part of the pelvis supports the body's weight?

See the blue Answers tab at the back of the book.

8-4 The bones of the lower limbs are adapted for movement and support

Learning Outcome Identify the bones of the lower limbs, their functions, and their surface features.

The skeleton of each lower limb consists of a *femur* (thigh), a *patella* (kneecap), a *tibia* and a *fibula* (leg), and the *tarsal bones*, *metatarsals*, and *phalanges* of the foot. Once again, anatomical terminology differs from common usage. Notice that in

anatomical terms, *leg* refers only to the distal portion of the limb, not to the entire lower limb. We use *thigh* and *leg*, rather than *upper leg* and *lower leg*.

The functional anatomy of the lower limbs differs from that of the upper limbs, primarily because the lower limbs transfer the body weight to the ground. For this reason, the bones of the lower limbs are more massive than those of the upper limbs. We now examine the bones of the right lower limb.

The Femur (Thighbone)

The **femur** is the longest and heaviest bone in the body. It is made up of three major parts (from proximal to distal): the *femoral head*, the *shaft*, and the *condyles* (**Figure 8–10a,b**). It articulates with the hip bone at the hip joint and with the tibia of the leg at the knee joint. The rounded epiphysis, or **head**

Figure 8–9 Divisions of the Pelvis.

of the femur, articulates with the hip bone at the acetabulum. A ligament attaches the acetabulum to the femur at the **fovea capitis**, a small pit in the center of the femoral head. The **neck** of the femur joins the **shaft** at an angle of about 125° .

The **greater** and **lesser trochanters** are large, rough projections that originate at the junction of the neck and shaft. The greater trochanter projects laterally; the lesser trochanter projects posteriorly and medially. These trochanters develop where large tendons attach to the femur. On the anterior surface of the femur, the raised **intertrochanteric** (in-ter-trō-kan-TER-ik) **line** marks the edge of the articular capsule (**Figure 8–10a**). This line continues around to the posterior surface as the **intertrochanteric crest**.

The **linea aspera** is a rough ridge that runs along the center of the posterior surface of the femoral shaft, marking the attachment site of powerful hip muscles (**Figure 8–10b**). As it nears the knee joint, the linea aspera divides into a pair of ridges (the *medial* and *lateral supracondylar ridges*) that continue to the projections of the **medial** and **lateral epicondyles** (**Figure 8–10a,b**).

Inferior to these epicondyles are the smoothly rounded **medial** and **lateral condyles**, which are part of the knee joint. The two condyles are separated by a deep **intercondylar fossa**. The medial and lateral condyles extend across the inferior surface of the femur, but the intercondylar fossa does not reach the anterior surface. The anterior and inferior surfaces of the

+ Clinical Note Hip Fracture

A *hip fracture*, or a “broken hip,” involves the femur, not a hip bone. The two types of hip fractures are femoral neck fractures and intertrochanteric fractures. In a femoral neck fracture, the head of the femur separates from the femur (and its blood supply). There is no disconnection to the blood supply in an intertrochanteric fracture. As a result, such fractures may be repaired with a metal plate and screws.

two condyles are separated by the **patellar surface**, a smooth articular surface over which the patella glides. The adductor tubercle is a surface marking for muscle attachment.

The Patella (Kneecap)

The **patella**, or kneecap, is a large sesamoid bone that forms within the tendon of the *quadriceps femoris*, a group of muscles that extends (straightens) the knee. The patella has a rough, convex anterior surface and a broad **base** (**Figure 8–11a**). The roughened surface reflects the attachment of the *quadriceps tendon* (anterior and superior surfaces) and the *patellar ligament* (anterior and inferior surfaces). The patellar ligament connects the **apex** of the patella to the tibia.

Figure 8–10 Bone Markings on the Right Femur.**Figure 8–11** The Right Patella and Patella with Femur.

Clinical Note Shin Splints

What do a runner, dancer, and military recruit have in common? The possibility of a painful stress injury of the tibia called *shin splints*. Muscles and tendons of the lower leg pull on bone when workout intensity increases, and inflammation is often the result. The tender, mildly swollen shin responds well to rest, ice, and over-the-counter pain relievers. Proper stretching and new shoes also help, as does cross training to vary the impact on the leg. Too much too soon is too hard on the tibia!

The posterior patellar surface (**Figure 8-11b**) has two concave facets (called the medial and lateral facets). These facets articulate with the medial and lateral condyles of the femur (**Figure 8-11c**). Normally, the patella glides across the patellar surface of the femur. Its direction of movement is superior-inferior (up and down), not medial-lateral (side to side).

The patellae are cartilaginous at birth. They start to ossify after the person begins walking, as thigh and leg movements become more powerful. Ossification usually begins at age 2 or 3 and ends around the time of puberty.

Bones of the Leg

The *tibia* (TIB-ē-uh) and *fibula* (FIB-ū-luh) together support the leg. The slender fibula parallels the lateral border of the tibia, with the tibia medial to the fibula in anatomical position. The medial border of the thin fibula is bound to the tibia by the **interosseous membrane**. This membrane helps stabilize the positions of the two bones. It also provides additional surface area for muscle attachment. A cross section of the tibia and fibula is shown in **Figure 8-12**.

The Tibia

The **tibia**, or shinbone, is the large medial bone of the leg; its main parts (from proximal to distal) are the *condyles*, the *shaft*, and a process called the *medial malleolus* (**Figure 8-12a**). The medial and lateral condyles of the femur articulate with the **medial** and **lateral tibial condyles** at the proximal end of the tibia. The **intercondylar eminence** is a ridge that separates the condyles (**Figure 8-12b**). The anterior surface of the tibia near the condyles has a prominent, rough **tibial tuberosity** (**Figure 8-12a**), which can be felt through the skin. This tuberosity marks the attachment of the patellar ligament.

The **anterior margin** is a ridge that begins at the tibial tuberosity and extends distally along the anterior tibial surface. The anterior margin of the tibia can be felt through the skin. As it nears the ankle joint, the tibia broadens, and the medial border ends in the **medial malleolus** (ma-LE-ō-lus; *malleolus*,

hammer), a large process familiar to some as the medial bump at the ankle. The inferior surface of the tibia articulates with the proximal bone of the ankle. The medial malleolus supports this joint medially.

The Fibula

From proximal to distal, the **fibula** is made up of a *head*, *shaft*, and *lateral malleolus* process (**Figure 8-12a,b**). The **head** of the fibula articulates with the tibia. The articular facet is located on the anterior, inferior surface of the lateral tibial condyle.

As its small diameter suggests, the fibula does not help transfer weight to the ankle and foot. In fact, it does not even articulate with the femur. However, the fibula is an important site for the attachment of muscles that move the foot and toes. In addition, the distal tip of the fibula extends laterally to the ankle joint. This fibular process, the **lateral malleolus**, gives lateral stability to the ankle. However, forceful movement of the foot outward and backward can dislocate the ankle, breaking both the lateral malleolus of the fibula and the medial malleolus of the tibia. This injury is called a *Pott's fracture*.

Tips

To remember how to distinguish the fibula from the tibia, consider the **fib** and **l** parts of the word *fibula*. To tell a small **lie** is to **fib**. The **fibula** is **smaller** than the tibia and is **lateral** to it.

Bones of the Ankle and Foot

The ankle, or *tarsus*, consists of seven *tarsal bones* (**Figure 8-13**). The *metatarsals* are five long bones that form the distal portion of the foot, or *metatarsus*. The toes of the foot contain 14 *phalanges*, or toe bones.

The Tarsal Bones

The **tarsal bones** make up the ankle. The large **talus** transfers the weight of the body from the tibia toward the toes. The articulation between the talus and the tibia occurs across the superior and medial surfaces of the **trochlea**, a spool- or pulley-shaped articular process. The lateral surface of the trochlea articulates with the lateral malleolus of the fibula.

Tips

To remember where the talus is located, think that the **talus** is on **top** of the foot and articulates with the **tibia**.

The **calcaneus** (kal-KĀ-nē-us), or heel bone, is the largest of the tarsal bones (**Figure 8-13a,b**). When standing, most body weight is transferred from the tibia through the talus to the calcaneus, and then to the ground. The posterior portion of the calcaneus is a rough, knob-shaped projection.

Figure 8–12 The Right Tibia and Fibula.

Which of the leg bones does not articulate with the femur?

This is the attachment site for the *calcaneal tendon* (*Achilles tendon*), which extends from the calf muscles. When standing, these strong muscles can lift the heels off the ground so that a person is standing on tiptoes. The superior and anterior surfaces of the calcaneus have smooth facets for articulation with other tarsal bones.

The **cuboid** articulates with the anterior surface of the calcaneus. The **navicular** is anterior to the talus, on the medial side of the ankle. It articulates with the talus and with the three *cuneiform* (kū-NĒ-i-form) bones. These wedge-shaped bones are arranged in a row, with articulations between them. They are named according to their position: **medial cuneiform**, **intermediate cuneiform**, and **lateral cuneiform**. Proximally, the cuneiform bones articulate with the anterior surface of the navicular. The lateral cuneiform also articulates

with the medial surface of the cuboid. The distal surfaces of the cuboid and the cuneiform bones articulate with the metatarsals of the foot.

Tips

To remember the names of the tarsal bones in the order presented in this text, try the memory aid “Tom Can Control Not Much In Life.”

The Metatarsals and Phalanges

The five **metatarsals** in the foot are identified by Roman numerals I–V, proceeding from medial to lateral across the sole (**Figure 8–13a,b**). Proximally, metatarsals I–III articulate with the three cuneiform bones, and metatarsals IV and V articulate

Figure 8–13 Bones of the Ankle and Foot.

with the cuboid. Distally, each metatarsal articulates with a different proximal phalanx.

The **phalanges** of the toes have the same anatomical organization as do those of the fingers (**Figure 8–13a,b**). The **hallux**, or great toe, has two phalanges (*proximal* and *distal*). The other four toes have three phalanges apiece (*proximal*, *middle*, and *distal*).

Clinical Note Stress Fractures

Running is beneficial to overall health but places the foot bones under more stress than does walking. *Stress fractures* are hairline fractures that develop in bones subjected to repeated shocks or impacts. Stress fractures of the foot usually involve one of the metatarsals. These fractures are caused either by improper placement of the foot while running or by poor arch support. In a fitness regime that includes street running, proper support for the bones of the foot is essential. The entire running-shoe market arose around the amateur and professional runner's need for good arch support.

Arches of the Foot

When standing or walking, the bones of the feet do not rest flat on the ground. Instead, weight transfer occurs along arches in the foot (**Figure 8–13c**) that are maintained by ligaments and tendons. There are two main types of arches, *longitudinal* and *transverse*.

The main **longitudinal arch** ties the calcaneus to the distal portions of the metatarsals. As a result, the medial plantar surface of the foot remains elevated, so that the muscles, nerves, and blood vessels that supply the inferior surface are not squeezed between the metatarsals and the ground. Note that the *lateral part* of the longitudinal arch has much less curvature than the *medial part*. Part of the reason is that the medial part has more elasticity. This elasticity absorbs the shocks from sudden changes in weight loading, for example, from the stresses that running or ballet dancing place on the toes. The **transverse arch** describes the degree of curvature change from one side of the foot to the other. In the condition known as *flatfeet*, normal arches are lost ("fall") or never form.

When standing, the body weight is distributed evenly between the calcaneus and the distal ends of the metatarsals. The amount of weight transferred forward depends on the position of the foot and the placement of the body weight. During flexion at the ankle, a movement called *dorsiflexion*,

+ Clinical Note Club Foot

The arches of the foot are usually present at birth. Sometimes, however, they fail to develop properly. In **club foot** (*congenital talipes equinovarus*), abnormal muscle development distorts growing bones and joints. One or both feet may be involved. The condition can be mild, moderate, or severe. In most cases, the tibia, ankle, and foot are affected. The longitudinal arch is exaggerated, and the feet are turned medially and inverted. If both feet are involved, the soles face one another. This condition affects 1 in 1000 births and is twice as common in males as females. Prompt treatment with casts or other supports in infancy helps alleviate the problem. Fewer than half the cases require surgery.

8

body weight rests on the calcaneus—as when a person “digs in their heels.” During extension at the ankle, a movement called *plantar flexion*, as when a person stands on tiptoe, the talus and calcaneus transfer the weight to the metatarsals and phalanges through the more anterior tarsal bones.

✓ Checkpoint

11. Identify the bones of the lower limb.
12. The fibula is not part of the knee joint and does not bear weight. However, when it is fractured, walking is difficult. Why?
13. While jumping off the back steps at his house, 10-year-old Kellen lands on his right heel and breaks his foot. Which foot bone is most likely broken?
14. Which foot bone transfers the weight of the body from the tibia toward the toes?

See the blue Answers tab at the back of the book.

8-5 Differences in sex and age account for individual skeletal variation

Learning Outcome Summarize sex differences and age-related changes in the human skeleton.

A comprehensive study of a human skeleton can reveal important information about a person. We can estimate a person's muscular development and muscle mass from the appearance of various ridges and from the general bone mass. Details such

as the condition of the teeth or the presence of healed fractures give an indication of the person's medical history. Two important facts, sex and age, can be determined or closely estimated on the basis of known measurements. In some cases, the skeleton may provide clues about a person's nutritional state, handedness, and even occupation.

Spotlight Figure 8-14 identifies characteristic relative differences between the skeletons of males and females. However, not every skeleton shows every feature detailed in this figure. Many differences, including bone markings on the skull, cranial capacity, and general skeletal features, reflect differences in average body size, muscle mass, and muscular strength. Note that differences in cranial capacity do not indicate any intellectual differences among people.

Some variations in the female pelvis appear to be adaptations for childbearing. These adaptations help support the weight of the developing fetus within the uterus and the passage of the newborn through the pelvic outlet during vaginal delivery. In addition, the hormone *relaxin*, produced during pregnancy, loosens the pubic symphysis and sacroiliac ligaments. This loosening allows movement between the hip bones that can further increase the size of the pelvic inlet and outlet. In cases where the fetus is too large to fit through the pelvic outlet, delivery is accomplished by cesarean section, or C-section. A C-section is a surgical incision made through the abdominal wall and uterus to deliver the newborn.

The general changes in the skeletal system that take place with age are summarized in **Table 8-1**. Note that these changes begin at age 3 months and continue throughout life. The epiphyseal cartilages, for example, begin to fuse at about age 3. The timing of epiphyseal closure is a key factor determining adult body size. Young people whose long bones are still growing should avoid heavy weight training, because they risk crushing the epiphyseal cartilages and thus shortening their stature (look back at **Spotlight Figure 6-11**). Degenerative changes in the normal skeletal system, such as a reduction in mineral content in the bony matrix, typically do not begin until age 30–45.

✓ Checkpoint

15. Compare and contrast the bones of males and females with respect to weight and bone markings.
16. An anthropologist discovered several bones in a deep grave. After close visual inspection and careful measurements, what sort of information could the bones reveal?
17. How is the female pelvis adapted for childbearing?

See the blue Answers tab at the back of the book.

Media resource available for this topic: Practice Anatomy Lab: Skeletal System: Appendicular Skeleton

The sex of an adult human skeleton can be determined by many of the details seen in the bones. The skull and pelvis are particularly helpful. Not every skeleton shows every feature clearly, but this chart contrasts the basic differences between the sexes.

MALE		SKULL	FEMALE	
	Heavier, rougher	General appearance	Lighter, smoother	
	About 10% larger	Cranium	About 10% smaller	
	More sloping	Forehead	More vertical	
	Larger	Sinuses	Smaller	
	Larger	Teeth	Smaller	
	Larger, squarer, more robust	Mandible	Smaller, narrower, less robust	
		PELVIS		
	Narrower, rougher, more robust	General appearance	Broader, smoother, less robust	
	More vertical; extends further superior to sacro-iliac joint	Ilium	Less vertical; less extension superior to sacral articulation	
	Long, narrow triangle with pronounced sacral curvature	Sacrum	Broad, short triangle with less sacral curvature	
	Deeper	Iliac fossa	Shallower	
	Narrower, heart shaped	Pelvic inlet	Open, circular shaped	
	Narrow	Pelvic outlet	Wide	
	Points anteriorly	Coccyx	Points inferiorly	
	Directed laterally	Acetabulum	Faces slightly anteriorly	
	Oval	Obturator foramen	Triangular	
	Less than 90°	Pubic angle	100° or more	
		OTHER		
Greater	Bone mass and density	Lesser		
More prominent	Bone markings	Less prominent		

Table 8–1 Age-Related Changes in the Skeleton

Region and Feature	Events	Age in Years
GENERAL SKELETON		
Bony matrix	Reduction in mineral content; increased risk of osteoporosis	Begins at ages 30–45; values differ for males versus females between ages 45 and 65; similar reductions occur in all people after age 65
Bone markings	Reduction in size, roughness	Gradual reduction with increasing age and decreasing muscular strength and mass
SKULL		
Fontanelles	Closure	Completed by age 2
Frontal suture	Fusion	2–8
Occipital bone	Fusion of ossification centers	1–4
Styloid process	Fusion with temporal bone	12–16
Hyoid bone	Complete ossification and fusion	25–30
Teeth	Loss of deciduous teeth (“baby teeth”); appearance of permanent teeth	Eruption of deciduous teeth (6 months to 2 years); eruption of permanent teeth (6 years to 21 years)
Mandible	Loss of teeth; reduction in bone mass; change in angle at mandibular notch	Accelerates in later years (60+)
VERTEBRAE		
Curvature	Development of major curves	3 months–10 years
Intervertebral discs	Reduction in size, percentage contribution to height	Accelerates in later years (60+)
LONG BONES		
Epiphyseal cartilages	Fusion	Begins about age 3; ranges vary, but general analysis permits determination of approximate age
PECTORAL AND PELVIC GIRDLES		
Epiphyses	Fusion	Relatively narrow ranges of ages (14–16, 16–18, 22–25) increase accuracy of age estimates

8 Chapter Review

Study Outline

An Introduction to the Appendicular Skeleton

1. The **appendicular skeleton** includes the bones of the upper and lower limbs and the pectoral and pelvic girdles, which connect the limbs to the trunk. (*Figure 8–1*)

8-1 The pectoral (shoulder) girdles attach the upper limbs to the axial skeleton

2. Each upper limb articulates with the trunk through a **pectoral girdle**, or *shoulder girdle*, which consists of a **scapula** and a **clavicle**.
3. On each side, a clavicle and scapula position the shoulder joint, help move the upper limb, and provide a base for muscle attachment. (*Figures 8–2, 8–3*)
4. Both the **coracoid process** and the **acromion** of the scapula have attached ligaments and tendons associated with the shoulder joint. (*Figure 8–3*)

Media Resources:

- Chapter Quizzes, Chapter Practice Test, MP3 Tutor Sessions, and Clinical Case Studies
- Practice Anatomy Lab
- Interactive Physiology
- A&P Flix
- PhysioEx

8-2 The bones of the upper limbs are adapted for free movement

5. The scapula articulates with the **humerus** at the shoulder (*glenohumeral*) joint. The **greater** and **lesser tubercles** of the humerus are important sites of muscle attachment. (*Figure 8–4*)
6. The humerus articulates with the **radius** and **ulna**, the bones of the forearm, at the elbow joint. (*Figure 8–5*)

7. The **carpal bones** of the wrist form two rows. The distal row articulates with the five **metacarpals**. Four of the fingers contain three **phalanges**; the **pollex** (thumb) has only two phalanges. (Figure 8-6)

8-3 The pelvic girdle (hips) attaches the lower limbs to the axial skeleton

8. The bones of the **pelvic girdle** are more massive than those of the pectoral girdle because of their role in weight bearing and locomotion.
9. The pelvic girdle consists of two **hip bones (coxal bones or pelvic bones)**. Each hip bone forms through the fusion of three bones: the **ilium**, **ischium**, and **pubis**. (Figure 8-7)
10. The ilium is the largest component of the hip bone. Inside the **acetabulum**, the ilium is fused to the ischium (posteriorly) and the pubis (anteriorly). The *pubic symphysis* limits movement between the pubic bones of the left and right hip bones. (Figures 8-7, 8-8)
11. The **pelvis** consists of the hip bones, the sacrum, and the coccyx. It is subdivided into the **false (greater) pelvis** and the **true (lesser) pelvis**. (Figures 8-8, 8-9)

8-4 The bones of the lower limbs are adapted for movement and support

12. The **femur** is the longest and heaviest bone in the body. It articulates with the **tibia** at the knee joint. (Figures 8-10, 8-12)

13. The **patella** is a large sesamoid bone. (Figure 8-11)
14. The **fibula** parallels the tibia laterally. (Figure 8-12)
15. The **tarsus**, or ankle, has seven **tarsal bones**. (Figure 8-13)
16. The basic organizational pattern of the **metatarsals** and **phalanges** of the foot resembles that of the hand. All the toes have three phalanges, except for the **hallux** (great toe), which has two. (Figure 8-13)
17. When a person stands, most of the body weight is transferred to the **calcaneus**, and the rest is passed on to the five metatarsals through the **talus**. Weight transfer occurs along the **longitudinal arch**. There is also a **transverse arch** that runs from one side of the foot to the other. (Figure 8-13)

8-5 Differences in sex and age account for individual skeletal variation

18. Studying a human skeleton can reveal important information, such as the person's weight, sex, body size, muscle mass, and age. (Spotlight Figure 8-14; Table 8-1)
19. Age-related changes take place in the skeletal system. These changes begin at about age 3 months and continue throughout life. (Table 8-1)

Review Questions

See the blue Answers tab at the back of the book.

LEVEL 1 Reviewing Facts and Terms

1. In the following photographs of the scapula, identify the three views (a-c) and the indicated bone markings (d-g).

- (a) _____ (b) _____
 (c) _____ (d) _____
 (e) _____ (f) _____
 (g) _____

2. Which part of the axial skeleton provides the only bony connection with the pectoral girdle? (a) first rib, (b) second rib, (c) second thoracic vertebra, (d) first thoracic vertebra, (e) sternum.

3. In the following drawing of the pelvis, label the structures indicated.

- (a) _____ (b) _____
 (c) _____ (d) _____
 (e) _____ (f) _____

4. In anatomical position, the scaphoid lies (a) medial to the lunate, (b) lateral to the lunate, (c) proximal to the radius, (d) distal to the hamate.
5. A typical site for a humerus fracture is the _____.
 (a) anatomical neck, (b) head, (c) surgical neck, (d) intertubercular sulcus.
6. The bones of the hand articulate distally with the (a) carpal bones, (b) ulna and radius, (c) metacarpals, (d) phalanges.
7. The epiphysis of the femur articulates with the pelvis at the (a) pubic symphysis, (b) acetabulum, (c) sciatic notch, (d) obturator foramen.
8. What is the name of the depression in which the deltoid tuberosity on the posterior surface of the humerus ends?
9. Name the structures that help in forming the pubic symphysis.
10. Which eight bones make up the wrist?

LEVEL 2 Reviewing Concepts

11. The ulnar nerve is prone to prickling because it crosses the humerus at the **(a)** medial epicondyle, **(b)** lateral epicondyle, **(c)** trochlea, **(d)** radial fossa.
12. The clavicle articulates with the scapula at the **(a)** superior angle, **(b)** inferior angle, **(c)** acromion, **(d)** coracoid process.
13. All are structural characteristics of the female pelvic girdle compared to the male pelvic girdle with either one or two exceptions. Identify the exception(s). **(a)** The female pelvis is adapted for childbearing. **(b)** The female pelvic girdle is lighter than the male pelvic girdle. **(c)** Relaxin produced by the male pelvic girdle loosens the pubic symphysis and sacro-iliac joints. **(d)** The shape of the female pelvic girdle is the same as that of the male. **(e)** Answers c and d are exceptions.
14. An important bone marking on the ilium is the **(a)** lesser sciatic notch, **(b)** greater sciatic notch, **(c)** pectineal line, **(d)** obturator foramen.
15. Which of the following skeletal characteristics is an adaption for childbearing? **(a)** inferior angle of 100° or more between the pubic bones, **(b)** a relatively broad, low pelvis, **(c)** less curvature of the sacrum and coccyx, **(d)** All of these are correct.
16. In case an athlete suffers a fractural dislocation of the ankle, the most likely parts of the skeleton to break is/are the **(a)** medial malleolus, **(b)** medial tibial condyle, **(c)** lateral malleolus, **(d)** lateral tibial condyle, **(e)** both a and c.
17. Hallux and pollex differ from the other toes and fingers because they have **(a)** more phalanges, **(b)** fewer phalanges, **(c)** no distal phalanx, **(d)** no proximal phalanx.
18. What is the difference between the true pelvis and the false pelvis?
19. What skeletal characteristic can be used to correctly determine a person's age?

20. Mary's physician tells her that the pain she is experiencing is due to a condition called carpal tunnel syndrome. Which part of Mary's body is aching? **(a)** her shoulder, **(b)** her hip, **(c)** her wrist, **(d)** her ankle, **(e)** her knee.
21. The pelvis **(a)** protects the upper abdominal organs, **(b)** contains bones from both the axial and appendicular skeletons, **(c)** is composed of the coxal bones, sacrum, and coccyx, **(d)** does all of these, **(e)** does b and c.
22. Why are shoulders very mobile but not very strong?
23. In determining the age of a skeleton, all of the following pieces of information would be helpful *except* **(a)** the number of cranial sutures, **(b)** the size and roughness of the markings of the bones, **(c)** the presence or absence of fontanelles, **(d)** the presence or absence of epiphyseal cartilages, **(e)** the types of minerals deposited in the bones.

LEVEL 3 Critical Thinking and Clinical Applications

24. Why would a person with osteoporosis be more likely to fracture a hip than a shoulder?
25. After a fall, Jake is brought to the hospital, where a fracture of the humerus is diagnosed. The doctor calls the site of Jake's injury the surgical neck of the bone. Where is the surgical neck situated, and why is it called so?
26. Investigators find the pelvis of a human and can identify the sex, the relative age, and some physical characteristics of the person. How is this possible from only the pelvis?

8

**CLINICAL CASE Wrap-Up Head Over Heals**

The x-ray showed that Sipho had fractured his right clavicle when he fell off his bicycle. A broken clavicle is a common injury associated with cycling accidents like Sipho's, and in other accidents where people put out their arm to try to break a fall. Fractures of the clavicle most often occur in the middle of the bone, although in Sipho's case the x-ray showed that his clavicle was fractured closer to the sternoclavicular (proximal) end; hence, the swelling in that area.

Treatment for Sipho involved using a clavicular strap to reposition and realign the clavicle and allow the ends of the fracture to knit, and he was also given pain medication. Sipho did not experience any further complications

from his injury and made a full recovery. However, in some cases a fracture of the clavicle may damage deeper structures such as the subclavian artery and vein and if the fracture is at the lateral end, then underlying nerves may be affected. A fracture of the clavicle may also puncture a lung, which would be a serious complication.

1. How would movement be affected if a clavicular fracture does not heal properly?
2. If a clavicular fracture damages the nerves underlying the clavicle, which part of the body is likely to be affected?

See the blue Answers tab at the back of the book.

Related Clinical Terms

bone bruise: Bleeding within the periosteum of a bone.

bone graft: A surgical procedure that transplants bone tissue to repair and rebuild diseased or damaged bone.

genu valgum: Deformity in which the knees angle medially and touch one another while standing; commonly called knock-kneed.

pelvimetry: Measurement of the dimensions of the female pelvis.

9

Joints

Learning Outcomes

These Learning Outcomes correspond by number to this chapter's sections and indicate what you should be able to do after completing the chapter.

- 9-1 ■ Contrast the major categories of joints and explain the relationship between structure and function for each category.
- 9-2 ■ Describe the basic structure of a synovial joint and describe common synovial joint accessory structures and their functions.
- 9-3 ■ Describe how the anatomical and functional properties of synovial joints permit movements of the skeleton.
- 9-4 ■ Describe the joints between the vertebrae of the vertebral column.
- 9-5 ■ Describe the structure and function of the elbow joint and the knee joint.
- 9-6 ■ Describe the structure and function of the shoulder joint and the hip joint.
- 9-7 ■ Describe the effects of aging on joints and discuss the most common age-related clinical problems for joints.
- 9-8 ■ Explain the functional relationships between the skeletal system and other body systems.

CLINICAL CASE

What's the Matter with the Birthday Girl?

Tatiana just woke up from her nap at preschool. Earlier this morning the class celebrated her fourth birthday with cupcakes and singing. Now she cries when she tries to roll over. Her best friend coaxes her to get up. “Come on, Tatiana, let’s play tag,” she says. Tatiana shakes her head “no,” and struggles to sit up on the side of the cot. She lets her feet dangle but won’t put her weight on her legs.

she reaches an arm out to help pull Tatiana up, Tatiana winces with pain.

A short while later, when Tatiana’s mother comes to pick her up, the teacher draws her aside for a quick conference. “Tatiana has not been participating in any play activities this whole week,” reports the teacher. “Even today, on her birthday, she refused to play tag. She takes a long time getting up from the floor after story circle. And her legs seemed to be hurting her after naptime. I wonder what’s going on?”

What’s the matter with Tatiana? To find out, turn to the Clinical Case Wrap-Up at the end of the chapter.

An Introduction to Joints

In this chapter we consider the ways bones interact whenever they meet at **joints**, or **articulations**. In the previous two chapters, you learned the individual bones of the skeleton and that they provide strength, support, and protection for softer tissues of the body. However, daily life demands more of the skeleton—it must also facilitate and adapt to body movements. Think of activities in a typical day, such as breathing, talking, walking, sitting, standing, and changing positions countless times. In each case, the skeleton is directly involved. Movements can occur only at joints because the bones of the skeleton are inflexible. The characteristic structure of a joint determines the type and amount of movement that may take place. Each joint reflects a compromise between the need for strength and stability and the need for mobility.

In this chapter we compare the relationships between articular form and function. We consider several examples that range from relatively immobile but very strong joints (the intervertebral joints) to a highly mobile but relatively weak joint (the shoulder).

9-1 Joints are categorized according to their structure or range of motion

Learning Outcome Contrast the major categories of joints and explain the relationship between structure and function for each category.

We use two classifications for joints: structural and functional. The former relies on the anatomy of the joint, whereas the latter is based on the amount of movement possible at a joint, a property known as the *range of motion*.

In terms of structure, we classify joints as *fibrous*, *cartilaginous*, *bony*, or *synovial*. Bony joints form when fibrous or cartilaginous joints ossify. The ossification may be normal or abnormal and may occur at various times in life. (We discuss synovial joints in more detail shortly.)

In terms of function, we first consider the range of motion for a joint. Such descriptions produce groups of immovable, slightly movable, and freely movable joints. Then each of these groups is further subdivided based on the anatomy of the joint, giving us this final classification (shown in more detail in **Table 9-1**):

- An *immovable joint* is a **synarthrosis** (sin-ar-THRŌ-sis; *syn*, together + *arthros*, joint). A synarthrosis can be *fibrous* or *cartilaginous*, depending on the type of connection formed by the two bones in the joint. Over time, these two bones may fuse (ossify), forming a bony joint.
- A *slightly movable joint* is an **amphiarthrosis** (am-fē-ar-THRŌ-sis; *amphi*, on both sides). An amphiarthrosis is either *fibrous* or *cartilaginous*, depending on the type of the connection between the opposing bones.
- A *freely movable joint* is a **diarthrosis** (dī-ar-THRŌ-sis; *dia*, through), or *synovial joint*. Diarthroses are subdivided functionally, according to their planes of movement (which we cover in Section 9-3).

The two classification schemes are loosely correlated. There are many anatomical patterns among immovable or slightly movable joints, but there is only one type of freely movable joint—synovial joints. All synovial joints are diarthroses, and the two terms are interchangeable. As you will read, synarthroses and amphiarthroses are found largely in the axial skeleton, whereas diarthroses predominate in the appendicular skeleton. We use the functional classification rather than the anatomical one in this chapter, because our primary interest is in how joints work.

Table 9–1 Functional and Structural Classifications of Joints

Functional Category	Structural Category and Type	Description
SYNARTHROSIS (no movement) At a synarthrosis, the bony edges are quite close together and may even interlock. These extremely strong joints are located where movement between the bones must be prevented.	FIBROUS Suture 	A suture (<i>sutura</i> , a sewing together) is a synarthrotic joint located only between the bones of the skull. The edges of the bones are interlocked and bound together at the suture by dense fibrous connective tissue.
	Gomphosis 	A gomphosis (gom-FŌ-sis; <i>gomphos</i> , bolt) is a synarthrosis that binds the teeth to bony sockets in the maxillae and mandible. The fibrous connection between a tooth and its socket is a <i>periodontal</i> (per-ē-ō-DON-tal; <i>peri</i> , around + <i>odontos</i> , tooth) <i>ligament</i> .
	CARTILAGINOUS Synchondrosis 	A synchondrosis (sin-kon-DRŌ-sis; <i>syn</i> , together + <i>chondros</i> , cartilage) is a rigid, cartilaginous bridge between two articulating bones. The cartilaginous connection between the ends of the first pair of vertebrosteral ribs and manubrium of the sternum is a synchondrosis. Another example is the epiphyseal cartilage, which connects the diaphysis to the epiphysis in a growing long bone.
	BONY Synostosis 	A synostosis (sin-os-TŌ-sis) is a totally rigid, immovable joint created when two bones fuse and the boundary between them disappears. The rare frontal (metopic) suture of the frontal bone, the fusion of an infant's left and right mandibular bones, and the epiphyseal lines of mature long bones are synostoses.
AMPHIARTHROSIS (little movement) An amphiarthrosis permits more movement than a synarthrosis but is much stronger than a freely movable joint. The articulating bones are connected by collagen fibers or cartilage.	FIBROUS Syndesmosis 	At a syndesmosis (sin-dez-MŌ-sis; <i>syndesmos</i> , ligament), bones are connected by a ligament. One example is the distal joint between the tibia and fibula.
	CARTILAGINOUS Symphysis 	At a symphysis , the articulating bones are connected by a wedge or pad of fibrocartilage. The joint between the two pubic bones (the <i>pubic symphysis</i>) is an example of a symphysis.
DIARTHROSIS (free movement) Planes of Movement ■ Monaxial: movement in one plane; elbow, ankle ■ Biaxial: movement in two planes; ribs and wrist ■ Triaxial: movement in three planes; shoulder, hip	SYNOVIAL 	Synovial (si-NŌ-ve-ul) joints permit a wider range of motion than do other types of joints. They are typically located at the ends of long bones, such as those of the upper and lower limbs.

✓ Checkpoint

1. Name and describe the three types of joints as classified by range of motion.
2. What characteristics do typical synarthrotic and amphiarthrotic joints share?
3. In a newborn, the large bones of the skull are joined by fibrous connective tissue. The bones later grow, interlock, and form immovable joints. Structurally, which type of joints are these?

See the blue Answers tab at the back of the book.

9-2 Diarthroses: Synovial joints contain synovial fluid and are surrounded by a joint capsule and stabilizing accessory structures

Learning Outcome Describe the basic structure of a synovial joint and describe common synovial joint accessory structures and their functions.

Synovial joints are freely movable diarthroses. A two-layered **joint capsule**, also called an **articular capsule**, surrounds the synovial joint (**Figure 9-1**). This capsule is continuous with the periosteum of the articulating bones. The joint capsule contains

an inner *synovial membrane* and an outer *fibrous capsule*. This membrane does not cover the articulating surfaces within the joint, which are protected by *articular cartilage*. Recall that a synovial membrane consists of areolar tissue covered by an incomplete epithelial layer. The *synovial fluid* that fills the *joint cavity* originates in the areolar tissue of the synovial membrane.

Remember that a joint cannot be both highly mobile and very strong. The greater the range of motion at a joint, the weaker it becomes. A synarthrosis is the strongest type of joint, but it permits no movement. In contrast, a diarthrosis, such as the shoulder joint, is far weaker but has a broad range of motion. Because of this relative weakness, synovial joints are surrounded by a variety of stabilizing *accessory structures*.

Now let's discover the major features of synovial joints.

Articular Cartilage

Under normal conditions, the bony surfaces at a synovial joint cannot contact one another, because special **articular cartilage** covers the articulating surfaces. Articular cartilage resembles hyaline cartilage found elsewhere in the body. However, articular cartilage has no perichondrium (a fibrous sheath described in Chapter 4), and the matrix contains more water than that of other cartilage.

Figure 9-1 The Structure of a Synovial Joint.

What structure covers the bony surfaces of a synovial joint to prevent the surfaces from touching?

The surface of articular cartilage is slick and smooth. This feature alone can reduce friction during movement at the joint. However, even when pressure is applied across a joint, the smooth articular cartilages do not touch one another because a thin film of synovial fluid within the joint cavity separates them (**Figure 9–1a**). This fluid acts as a lubricant, minimizing friction.

Synovial joints cannot function normally if the articular cartilages are damaged. When such damage occurs, the cartilage matrix may begin to break down. The exposed surface will then change from a slick, smooth-gliding surface to a rough abrasive surface of bristly collagen fibers. This abrasive surface drastically increases friction at the joint.

Synovial Fluid

What is synovial fluid? It is a clear, viscous solution with the consistency of egg yolk or heavy molasses. **Synovial fluid** resembles interstitial fluid but contains proteoglycans with a high concentration of hyaluronan secreted by fibroblasts of the synovial membrane. Even in a large joint such as the knee, the total quantity of synovial fluid in a joint is small—normally less than 3 mL (about one-tenth a fluid ounce).

The synovial fluid within a joint has the following primary functions:

- **Lubrication.** Articular cartilages act like sponges filled with synovial fluid. When part of an articular cartilage is compressed, some of the synovial fluid is squeezed out of the cartilage and into the space between the opposing surfaces. This thin layer of fluid greatly reduces friction between moving surfaces, just as a thin film of water makes a highway slick by reducing friction between a car's tires and the road. When the compression stops, synovial fluid is pulled back into the articular cartilage.
- **Nutrient Distribution.** The synovial fluid in a joint must circulate continuously to provide nutrients and a waste disposal route for the chondrocytes of the avascular articular cartilage. Whenever the joint moves, the compression and reexpansion of the articular cartilage pump synovial fluid into and out of the cartilage matrix. As the synovial fluid flows through the areolar tissue of the synovial membrane, additional nutrients are delivered and wastes are absorbed by diffusion across capillary walls.
- **Shock Absorption.** Synovial fluid cushions joints that are subjected to compression from shocks and sudden impacts. This occurs because the viscosity of synovial fluid increases with increased pressure. For example, the hip, knee, and ankle joints are compressed during walking. They are even more compressed when jogging or running. When the pressure across a joint suddenly increases, the resulting shock is lessened as the viscosity of synovial fluid increases.

As the pressure lessens, viscosity decreases and it regains its lubricating function across the articular surfaces.

Accessory Structures

Synovial joints may have a variety of protective and stabilizing accessory structures, including pads of cartilage or fat, ligaments, tendons, and *bursae* (protective pockets). **Figure 9–1b** details these structures in the knee joint.

Cartilages and Fat Pads

In several joints, including the knee, pads made of fibrocartilage or fat may lie between the opposing articular surfaces. A fibrocartilage pad called a **meniscus** (me-NIS-kus; a crescent; plural, *menisci*; me-NIS-kē) is located between opposing bones within a synovial joint. Menisci may subdivide a synovial cavity, channel the flow of synovial fluid, or allow for variations in the shapes of the articular surfaces.

Fat pads are localized masses of adipose tissue covered by a layer of synovial membrane. They are commonly superficial to the joint capsule. Fat pads protect the articular cartilages and act as packing material for the joint. When the bones move, the fat pads fill in the spaces created as the joint cavity changes shape.

Ligaments

Accessory **ligaments** are localized thickenings that support, strengthen, and reinforce synovial joints. *Extracapsular ligaments* are outside the joint capsule, while *intracapsular ligaments* are inside the joint capsule.

In a **sprain**, a ligament is stretched so much that some of the collagen fibers are torn, but the ligament survives and the joint is not damaged. With excessive force, one of the attached bones often breaks before the ligament tears. In general, a broken bone heals much more quickly and effectively than does a torn ligament. This is because ligaments have no direct blood supply and thus must obtain essential substances by the slow process of diffusion.

Tendons

Tendons are not part of the joint itself, but they do play a role in stabilizing the joint, because tendons connect the fleshy part of muscles to bones that make up the joint. Furthermore, tendons passing across or around a joint may limit the joint's range of motion yet provide mechanical support for it. For example, tendons associated with the muscles of the arm help brace the shoulder joint.

Bursae

Bursae (BUR-sē; singular, *bursa*; a pouch) are small, thin, fluid-filled pockets in connective tissue that reduce friction and act as shock absorbers. They contain synovial fluid and are lined

by a synovial membrane. Bursae may be connected to the joint cavity or may be separate from it. They form where a tendon or ligament rubs against other tissues. Bursae are located around most synovial joints, including the shoulder joint. *Synovial tendon sheaths* are tubular bursae that surround tendons where they cross bony surfaces. Bursae may also appear deep to the skin, covering a bone or lying within other connective tissues exposed to friction or pressure. Bursae that develop in abnormal locations, or because of abnormal stresses, are called *adventitious bursae*.

Factors That Stabilize Synovial Joints

9

For any synovial joint, movement beyond its normal range of motion will cause damage. Several factors are responsible for limiting a joint's range of motion, stabilizing it, and reducing the chance of it being injured:

- The collagen fibers of the joint capsule and any accessory, extracapsular, or intracapsular ligaments
- The shapes of the articulating surfaces and menisci, which may prevent movement in specific directions
- The presence of other bones, skeletal muscles, or fat pads around the joint
- Tension in tendons attached to the articulating bones.

When a skeletal muscle contracts and pulls on a tendon on a bone in a joint, movement in a specific direction is either encouraged or opposed. The pattern of stabilizing structures versus degree of mobility varies among joints. In general, the more stable the joint, the more restricted its range of motion. For example, the hip joint is stabilized by the shapes of the bones (the head of the femur projects into the acetabulum of the hip bone), a heavy capsule, intracapsular and extracapsular ligaments, tendons, and massive muscles. It is therefore very strong and stable. In contrast, the elbow is another stable joint, but it gains its stability from

Clinical Note Dislocation

A **dislocation** occurs when reinforcing structures cannot protect a joint from extreme stresses. In a dislocation, there is complete loss of contact between the articulating surfaces. Articular cartilages are damaged, ligaments tear, and the joint capsule is distorted. The *inside* of a joint has no pain receptors, but nerves that monitor the capsule, ligaments, and tendons are quite sensitive, so dislocations are very painful.

the interlocking shapes of the articulating bones. The capsule and associated ligaments provide additional support. Finally, the shoulder joint, as the most mobile synovial joint, relies primarily on the surrounding ligaments, muscles, and tendons for stability. For this reason, it is also weak.

Checkpoint

4. Describe the components of a synovial joint and identify the functions of each.
5. Why would improper circulation of synovial fluid lead to the degeneration of articular cartilages in the affected joint?
6. Define dislocation.

See the blue Answers tab at the back of the book.

9-3 Diarthroses: The different types of synovial joints allow a wide range of skeletal movements

Learning Outcome Describe how the anatomical and functional properties of synovial joints permit movements of the skeleton.

Range of motion (ROM) refers to the full movement at a particular joint. This range is usually the distance between flexion (decreasing the angle) and extension (increasing the angle). If a person has limited ROM, that means a joint cannot move through its normal range of movement. In this section, the terms *movement* and *motion* are used interchangeably.

Types of Movements at Synovial Joints

To describe human movement, we need a frame of reference that enables accurate and precise communication. In descriptions of movement at synovial joints, phrases such as “bend the leg” or “raise the arm” are imprecise. Anatomists use descriptive terms that have specific meanings. **Spotlight Figure 9-2a** provides a simple way to model these different types of movements with a pencil and representative articular surface.

Gliding Movement

In a gliding movement, two opposing surfaces slide past one another in one plane. Gliding occurs between the flat or nearly

Clinical Note Bursitis and Bunions

Bursae are normally flat and contain a small amount of synovial fluid. When injured, however, they become inflamed and swell with synovial fluid. This causes pain in the affected area whenever the tendon or ligament moves, resulting in a condition called **bursitis**. Inflammation can result from the friction due to repetitive motion, pressure over the joint, infection, or trauma. Bursitis associated with repetitive motion typically occurs at the shoulder. Musicians, golfers, baseball pitchers, and tennis players may develop bursitis there. The most common pressure-related bursitis is a **bunion**. Bunions may form over the base of the great toe because of friction and distortion of the first metatarsophalangeal joint. High heels and tight, pointy-toed shoes are often the culprit.

flat surfaces of articulating carpal bones, between tarsal bones, and between the clavicles and the sternum. The movement can occur in almost any direction, but the amount of movement is slight, and rotation is generally prevented by the capsule and associated ligaments.

Angular Movement

Examples of angular movement include *flexion*, *extension*, *abduction*, and *adduction* (Figure 9–3). Descriptions of these movements are based on reference to an individual in the anatomical position.

Figure 9–3 Angular Movements and Circumduction. The red dots indicate the locations of the joints involved in the movements illustrated.

List the various types of angular movements.

a Simple Model of Articular Motion

Take a pencil as your model and stand it upright on the surface of a desk. The pencil represents a bone, and the desk is an articular surface. A lot of twisting, pushing, and pulling will demonstrate that there are only three ways to move the pencil.

Moving the Point

Linear motion

Possible movement 1 shows the pencil can move. If you hold the pencil upright, without securing the point, you can push the pencil across the surface. This kind of motion is called **gliding**. You could slide the point forward or backward, from side to side, or diagonally.

Changing the Shaft Angle

Angular motion

Possible movement 2 shows the pencil shaft can change its angle with the surface. With the tip held in position, you can move the eraser end of the pencil forward and backward, from side to side, or at some intermediate angle.

Circumduction

A more complex angular motion is possible. Grasp the pencil eraser and move the pencil in any direction until it is no longer vertical. Now, swing the eraser through a complete circle in a movement called **circumduction**.

Rotating the Shaft

Rotation

Possible movement 3 shows that the pencil shaft can rotate. If you keep the shaft vertical and the point at one location, you can still spin the pencil around its longitudinal axis in a movement called **rotation**. No joint can freely rotate because this would tangle blood vessels, nerves, and muscles, as they crossed the joint.

b Axes of Motion

Movement of joints can also be described by the number of axes that they can rotate around. A joint that permits movement around one axis is called **monaxial**, a joint that permits movement around two axes is called **biaxial**, and one that permits movement around three axes is called **triaxial**.

Superior-inferior axis

Lateral-medial axis

Anterior-posterior axis

Classification of Synovial Joints

Synovial joints are freely movable diarthrotic joints, and they are classified by the type and range of motion permitted. Synovial joints are described as plane, hinge, condylar, saddle, pivot, or ball-and-socket on the basis of the shapes of the articulating surfaces, which in turn determines the joint movement.

Plane joint

Plane joints, or gliding joints, have flattened or slightly curved surfaces that slide across one another, but the amount of movement is very slight.

Movement:
Gliding.
Slight nonaxial

Examples:

- Acromioclavicular and claviculosternal joints
- Intercarpal joints
- Vertebrocostal joints
- Sacro-iliac joints

Hinge joint

Hinge joints permit angular motion in a single plane, like the opening and closing of a door.

Movement:
Angular.
Monaxial

Examples:

- Elbow joint
- Knee joint
- Ankle joint
- Interphalangeal joint

Condylar joint

Condylar joints, or ellipsoid joints, have an oval articular face nestled within a depression on the opposing surface.

Movement:
Angular.
Biaxial

Examples:

- Radiocarpal joint
- Metacarpophalangeal joints 2–5
- Metatarsophalangeal joints

Saddle joint

Saddle joints have complex articular faces and fit together like a rider in a saddle. Each face is concave along one axis and convex along the other.

Movement:
Angular.
Biaxial

Examples:

- First carpometacarpal joint

Pivot joint

Pivot joints only permit rotation.

Movement:
Rotation.
Monaxial

Examples:

- Atlanto-axial joint
- Proximal radio-ulnar joint

Ball-and-socket joint

In a ball-and-socket joint, the round head of one bone rests within a cup-shaped depression in another.

Movement:
Angular,
circumduction,
and rotation.
Triaxial

Examples:

- Shoulder joint
- Hip joint

Flexion and Extension. **Flexion** (FLEK-shun) is movement in the anterior–posterior (sagittal) plane that decreases the angle between articulating bones. **Extension** occurs in the same plane, but it increases the angle between articulating bones (**Figure 9–3a**). We usually apply these terms to the movements of the long bones of the limbs, but we can also use them to describe movements of the axial skeleton. For example, bringing the head toward the chest flexes the intervertebral joints of the neck. Bending down to touch the toes flexes the intervertebral joints of the spine. Extension reverses these movements, returning the body to the anatomical position.

When a person is in the anatomical position, the major joints of the axial and appendicular skeletons (except the ankle) are at full extension. (Terms to describe movements of the ankle joint are introduced later.) Flexion of the shoulder joint or hip joint moves the limbs anteriorly, whereas extension moves them posteriorly. Flexion of the wrist joint moves the hand anteriorly, and extension moves it posteriorly.

In each of these examples, extension can be continued past the anatomical position. Extension beyond the normal anatomical limit is called **hyperextension** (**Figure 9–3a**). Hyperextension of a limb cannot be done naturally without causing damage. Ligaments, bony processes, or soft tissues prevent hyperextension of many joints, such as the elbow or the knee.

Abduction and Adduction. **Abduction** (*ab-*, away, from) is movement *away* from the longitudinal axis (midline) of the body in the frontal plane (**Figure 9–3b**). For example, swinging the upper limb to the side is abduction of the limb. Moving it back to the anatomical position is **adduction** (*ad-*, towards). Adduction of the wrist moves the heel of the hand and fingers *toward* the body, whereas abduction moves them farther away. Spreading the fingers or toes apart abducts them, because they move *away from* a central digit (**Figure 9–3c**). Bringing them together is called adduction. (Fingers move toward or away from the middle finger; toes move toward or away from the second toe.) Abduction and adduction always refer to movements of the appendicular skeleton, not to those of the axial skeleton.

Tips

When someone is **abducted**, they are taken away, just as **abduction** takes the limb away from the body. During **adduction**, the limb is **added** to the body.

Circumduction

Circumduction is a complete circular movement. Moving the arm in a loop is circumduction, as when drawing a large circle on a whiteboard (**Figure 9–3d**). The hand moves in a circle, but the arm does not rotate.

Figure 9–4 Rotational Movements.

Rotational Movement

We also describe rotational movements with reference to a person in the anatomical position. Rotation of the head may involve *left rotation* or *right rotation* (**Figure 9–4a**). We describe limb rotation by reference to the longitudinal axis of the trunk. During **medial rotation**, also known as *internal rotation*, the anterior surface of a limb turns toward the long axis of the

trunk (**Figure 9-4a**). The reverse movement is called **lateral rotation**, or *external rotation*.

The proximal joint between the radius and the ulna permits rotation of the radial head. As the shaft of the radius rotates, the distal epiphysis of the radius rolls across the anterior surface of the ulna. This movement, called **pronation** (prō-NĀ-shun), turns the wrist and hand from palm facing front to palm facing back (**Figure 9-4b**). The opposing movement, in which the palm is turned anteriorly, is **supination** (sū-pi-NĀ-shun). The forearm is supinated in the anatomical position. This view makes it easier to follow the path of the blood vessels, nerves, and tendons, which rotate with the radius during pronation.

Tips

To carry a bowl of *soup*, the hand must be *supinated*.

Special Movements

Several special terms apply to movement at specific joints (**Figure 9-5**):

- **Inversion** (*in*, into + *vertere*, to turn) is a twisting movement of the foot that turns the sole inward, elevating

the medial edge of the sole. The opposite movement is called **eversion** (ē-VER-zhun) (**Figure 9-5a**).

- **Dorsiflexion** is flexion at the ankle joint and elevation of the sole, as when digging in the heel. **Plantar flexion** (*plantaris*, sole), the opposite movement, extends the ankle joint and elevates the heel, as when standing on tiptoe (**Figure 9-5b**). However, it is also acceptable (and simpler) to use “flexion and extension at the ankle,” rather than “dorsiflexion and plantar flexion.”
- **Opposition** is movement of the thumb toward the surface of the palm or the pads of other fingers (**Figure 9-5c**). Opposition enables grasping and holding objects between the thumb and palm. It involves movement at the first carpometacarpal and metacarpophalangeal joints. Flexion at the fifth metacarpophalangeal joint can assist this movement. **Reposition** is the movement that returns the thumb and fingers from opposition.
- **Protraction** is movement of a body part anteriorly in the horizontal plane. **Retraction** is the reverse movement. A person protracts their jaw when they jut the chin forward, and they retract the jaw when returning it to its normal position (**Figure 9-5d**).

Figure 9-5 Special Movements.

- **Depression** and **elevation** take place when we move a structure inferiorly and superiorly, respectively. The mandible is depressed when the mouth is opened, and the mandible is elevated when the mouth is closed (**Figure 9-5e**). Another familiar elevation takes place with shoulder shrugging.
- **Lateral flexion** occurs when the vertebral column bends to the side (**Figure 9-5f**). This movement is most pronounced in the cervical and thoracic regions.

Classification of Synovial Joints

Spotlight Figure 9-2b shows how the movement of synovial joints can be described by one to three axes of motion.

Synovial joints are classified by the type and ranges of motion they permit. **Spotlight Figure 9-2c** shows the six basic categories of synovial joints, which are based on the structure of the articular surfaces. These categories are *plane* (*gliding*), *hinge*, *condylar* (*ellipsoid*), *saddle*, *pivot*, and *ball-and-socket* joints. Please study this figure before going on in the chapter.

Checkpoint

7. Identify the types of synovial joints based on the shapes of the articulating surfaces.
8. When a person is doing jumping jacks, which lower limb movements are necessary?
9. Which movements are associated with hinge joints?

See the blue Answers tab at the back of the book.

9-4 Intervertebral joints contain intervertebral discs and ligaments that allow for vertebral movements

Learning Outcome Describe the joints between the vertebrae of the vertebral column.

The articulations between adjacent vertebrae form two types of joints—symphyses and synovial—that permit small movements associated with flexion and rotation of the vertebral column (**Figure 9-6a**). Little movement occurs between adjacent vertebral bodies. From axis to sacrum, the vertebrae are separated and cushioned by pads of fibrocartilage called *intervertebral discs*. Thus, the bodies of vertebrae form symphyses.

Intervertebral discs and symphyses are not found between the first and second cervical vertebrae or in the sacrum or coccyx, where vertebrae have fused. Recall that the first cervical vertebra has no vertebral body and no intervertebral disc. The only joint between the first two cervical vertebrae is a synovial joint that allows much more rotation than the symphyses between other cervical vertebrae.

Structure of Intervertebral Joints

Intervertebral joints are joints between adjacent vertebral bodies (these are symphyses) and joints between adjacent articular processes (these are synovial) along the vertebral column. Let's look at the structure of the intervertebral discs and ligaments that support these joints.

Intervertebral Discs

Each **intervertebral disc** has a tough outer layer of fibrocartilage, the **anulus fibrosus** (AN-ū-lus fī-BRŌ-sus). The collagen fibers of this layer attach the disc to the bodies of adjacent vertebrae. The anulus fibrosus surrounds the **nucleus pulposus** (pul-PŌ-sus), a soft, elastic, gelatinous core. The nucleus pulposus gives the disc resiliency and enables it to absorb shocks. The superior and inferior surfaces of the disc are almost completely covered by thin **vertebral end plates** that are composed of hyaline cartilage and fibrocartilage (**Figure 9-6b**).

Movement of the vertebral column compresses the nucleus pulposus and displaces it in the opposite direction. This displacement permits smooth gliding movements between vertebrae while maintaining their alignment.

The intervertebral discs make a significant contribution to a person's height: They account for about one-quarter of the length of the vertebral column superior to the sacrum. As we grow older, the water content of the nucleus pulposus in each disc decreases. The discs gradually become less effective as cushions, and the chances of vertebral injury increase. Water loss from the discs also causes the vertebral column to shorten, accounting for the characteristic decrease in height as we get older.

Intervertebral Ligaments

Numerous strong ligaments are attached to the bodies and processes of all vertebrae, binding them together and stabilizing the vertebral column (**Figure 9-6b**). Ligaments interconnecting adjacent vertebrae include the following:

- The *ligamenta flava* are paired ligaments that connect the laminae of adjacent vertebrae.
- The *posterior longitudinal ligament* is a fibrous band that parallels the anterior longitudinal ligament and connects the posterior surfaces of adjacent vertebral bodies.
- The *interspinous ligaments* are bands of fibrous tissue that connect the spinous processes of adjacent vertebrae.
- The *supraspinous ligament* is a longitudinal fibrous band that is attached to the tips of the spinous processes of the vertebrae from C₇ to the sacrum. The *ligamentum nuchae*, which extends from vertebra C₇ to the base of the skull, is continuous with the supraspinous ligament.

Figure 9–6 Intervertebral Joints.

Within an intervertebral disc, which structure provides the tough outer layer of fibrocartilage and which structure provides the soft inner core for resiliency and shock absorption?

- The *anterior longitudinal ligament* is a wide fibrous band that connects the anterior surfaces of adjacent vertebral bodies.

Tips

The **interspinous** ligaments and **supraspinous** ligament are so named because they are attached to the **spinous** processes of the vertebrae.

Vertebral Movements

The following movements can take place across the intervertebral joints of the vertebral column: (1) flexion, or bending

anteriorly; (2) extension, or bending posteriorly; (3) lateral flexion, or bending laterally; and (4) rotation. **Table 9–2** summarizes information about intervertebral and other joints of the axial skeleton.

Checkpoint

10. What type of joint only permits slight movements?
11. Which regions of the vertebral column lack intervertebral discs? Explain why the absence of discs is significant.
12. Which vertebral movements are involved in (a) bending forward, (b) bending to the side, and (c) moving the head to signify “no”?

See the blue Answers tab at the back of the book.

Table 9–2 Joints of the Axial Skeleton

Element	Joint	Type of Joint	Movement
SKULL			
Cranial and facial bones of skull	Various	Synarthroses (suture or synostosis)	None
Maxilla/teeth and mandible/teeth	Alveolar	Synarthrosis (gomphosis)	None
Temporal bone/mandible	Temporomandibular	Combined plane joint and hinge diarthrosis	Elevation, depression, and lateral gliding
VERTEBRAL COLUMN			
Occipital bone/atlas	Atlanto-occipital	Condylar diarthrosis	Flexion/extension
Atlas/axis	Atlanto-axial	Pivot diarthrosis	Rotation
Other vertebral elements	Intervertebral (between vertebral bodies)	Amphiarthrosis (symphysis)	Slight movement
	Intervertebral (between articular processes)	Plane diarthrosis	Slight rotation and flexion/extension
L₅/sacrum	Between L ₅ body and sacral body	Amphiarthrosis (symphysis)	Slight movement
	Between inferior articular processes of L ₅ and articular processes of sacrum	Plane diarthrosis	Slight flexion/extension
Sacrum/hip bone	Sacro-iliac	Plane diarthrosis	Slight movement
Sacrum/coccyx	Sacrococcygeal	Plane diarthrosis (<i>may become fused</i>)	Slight movement
Coccygeal bones		Synarthrosis (synostosis)	No movement
THORACIC CAGE			
Bodies of T₁–T₁₂ and heads of ribs	Costovertebral	Plane diarthrosis	Slight movement
Transverse processes of T₁–T₁₀	Costovertebral	Plane diarthrosis	Slight movement
Ribs and costal cartilages		Synarthrosis (synchondrosis)	No movement
Sternum and first costal cartilage	Sternocostal (1st)	Synarthrosis (synchondrosis)	No movement
Sternum and costal cartilages 2–7	Sternocostal (2nd–7th)	Plane diarthrosis*	Slight movement

*Commonly converts to synchondrosis in older individuals.

9-5 The elbow and knee are both hinge joints

Learning Outcome Describe the structure and function of the elbow joint and the knee joint.

In this section we consider the structure and function of two major hinge joints: the elbow joint and the knee joint.

The Elbow Joint

The elbow joint is a complex hinge joint that involves the humerus, radius, and ulna (**Figure 9-7**). The largest and strongest articulation at the elbow is the *humero-ulnar joint*, where the trochlea of the humerus articulates with the trochlear notch of the ulna. This joint works like a door hinge, with physical limitations imposed on the range of motion. In the case of the elbow, the shape of the trochlear notch of the ulna determines the plane of movement, and the combination of the notch and the olecranon limits the degree of extension permitted. At the smaller *humero-radial joint*, the capitulum of the humerus articulates with the head of the radius.

Muscles that attach to the rough surface of the olecranon produce extension of the elbow. These muscles are mainly under the control of the *radial nerve*, which passes along the radial groove of the humerus. The large *biceps brachii* covers the anterior surface of the arm. Its distal tendon is attached to the radius at the radial tuberosity. Contraction of this muscle produces supination of the forearm and flexion at the elbow.

The elbow joint is extremely stable because (1) the bony surfaces of the humerus and ulna interlock, (2) a single, thick joint capsule surrounds both the humero-ulnar and proximal radio-ulnar joints, and (3) strong ligaments reinforce the joint capsule.

The *radial collateral ligament* stabilizes the lateral surface of the elbow joint (**Figure 9-7a**). It extends between the lateral epicondyle of the humerus and the *annular ligament*, which binds the head of the radius to the ulna. The *ulnar collateral ligament* stabilizes the medial surface of the elbow joint. This ligament extends from the medial epicondyle of the humerus anteriorly to the coronoid process of the ulna and posteriorly to the olecranon (**Figure 9-7b**).

Figure 9-7 The Right Elbow Joint Showing Stabilizing Ligaments.

a Lateral view

b Medial view

Despite the strength of the joint capsule and ligaments, the elbow can be damaged by severe impacts or unusual stresses. For example, if one falls on their hand with a partially flexed elbow, contractions of muscles that extend the elbow may break the ulna at the center of the trochlear notch. Less violent stresses can produce dislocations or other injuries to the elbow, especially if epiphyseal growth has not been completed. For example, parents in a rush may drag a toddler along behind them, exerting an upward, twisting pull on the elbow joint that can result in a partial dislocation of the radial head from the annular ligament known as *nursemaid's elbow*.

The Knee Joint

The knee joint transfers the weight of the body from the femur to the tibia. The knee joint functions as a hinge, but the joint is far more complex than the elbow or even the ankle. The rounded condyles of the femur roll across the superior surface of the tibia, so the points of contact are constantly changing. The joint permits flexion, extension, and very limited rotation.

The knee joint contains three separate articulations. Two are between the femur and tibia (medial condyle to medial condyle, and lateral condyle to lateral condyle). One is between the patella and the patellar surface of the femur (**Figure 9-8a**). Let's look at the joint itself and then its supporting accessory structures.

Joint Capsule and Joint Cavity

The joint capsule at the knee joint is thin and partially incomplete, but various ligaments and tendons of associated muscles strengthen it. A pair of fibrocartilage pads, the *medial* and *lateral menisci*, lies between the femoral and tibial surfaces (**Figures 9-1b, 9-8b**). The menisci (1) act as cushions, (2) conform to the shape of the articulating surfaces as the femur changes position, and (3) provide lateral stability to the joint. Prominent fat pads cushion the margins of the joint. These fat pads also assist the many bursae in reducing friction between the patella and other tissues.

Accessory Structures

A complete dislocation of the knee is very rare, mainly because seven major ligaments stabilize the knee joint:

1. The tendon from the *quadriceps femoris* passes over the anterior surface of the joint and is responsible for extending the knee when the muscle contracts. The patella is embedded in this tendon, and the *patellar ligament* continues to its attachment on the anterior surface of the tibia (**Figure 9-8a**). The patellar ligament and two ligamentous bands known as the *patellar retinaculæ* support the anterior surface of the knee joint.
- 2, 3. Two *popliteal ligaments* extend between the femur and the heads of the tibia and fibula (**Figure 9-8c**). These ligaments reinforce the knee joint's posterior surface.
- 4, 5. Inside the joint capsule, the *anterior cruciate* (KRŪ-she-at) *ligament* (ACL) and *posterior cruciate ligament* (PCL) attach the intercondylar area of the tibia to the condyles of the femur (**Figure 9-8d**). The "anterior" and "posterior" in these terms refer to the sites of origin of these ligaments on the tibia. They cross one another as they proceed to their destinations on the femur. (The term *cruciate* is derived from the Latin word *cruciatu*s, a cross.) The ACL and the PCL limit the anterior and posterior movement of the tibia and maintain the alignment of the femoral and tibial condyles.

Figure 9–8 The Right Knee Joint.

+ Clinical Note Damage to Intervertebral Discs

If the posterior longitudinal ligament is weakened, which often occurs as we age, intervertebral discs become more vulnerable to damage. The compressed nucleus pulposus of a disc may distort the anulus fibrosus, forcing it partway into the vertebral canal. This condition, shown here in lateral view, is called a **bulging disc** (Figure a). If the nucleus pulposus

breaks through the anulus fibrosus, it too may protrude into the vertebral canal. This condition, shown here in superior view, is called a **herniated disc** (Figure b). When a disc herniates, it compresses spinal nerves and may cause pain. Lumbar pain and disc disease are potential hazards for nurses, who often lift and transfer patients.

a A lateral view of the lumbar region of the spinal column, showing a bulging intervertebral disc

b A sectional view through a herniated disc, showing the release of the nucleus pulposus and its effect on the spinal cord and adjacent spinal nerves

9

6, 7. The *tibial collateral ligament* (clinically called the *medial collateral ligament* [MCL]) reinforces the medial surface of the knee joint, and the *fibular collateral ligament* (clinically called the *lateral collateral ligament* [LCL]) reinforces the lateral surface (Figure 9–8). These ligaments tighten only at full extension, the position in which they stabilize the joint.

At full extension, a slight lateral rotation of the tibia tightens the anterior cruciate ligament and wedges the lateral meniscus between the tibia and femur. The knee joint is essentially locked in the extended position. With the joint locked, a person can stand for prolonged periods without using (and tiring) the muscles that extend the knee. Unlocking the knee joint requires muscular contractions that medially rotate the tibia or laterally rotate the femur.

The knee joint is subjected to severe stresses during daily activities. Painful knee injuries are all too familiar to both amateur and professional athletes. Treatment is often costly and prolonged, and repairs seldom make the joint “good as new.”

✓ Checkpoint

13. Kai injures his forearm and elbow. After the injury, he notices an unusually large degree of motion between the radius and the ulna at the elbow. Which ligament did Kai most likely damage?
14. What signs and symptoms are expected in a person who has damaged the menisci of the knee joint?
15. Why is “clergyman’s knee” (a type of bursitis) common among carpet layers and roofers?
16. Name the bones making up the knee joint.

See the blue Answers tab at the back of the book.

9-6 The shoulder and hip are both ball-and-socket joints

Learning Outcome Describe the structure and function of the shoulder joint and the hip joint.

Here we examine the ball-and-socket joints of the body: the shoulder joint and the hip joint.

+ Clinical Note Knee Injuries

Athletes place tremendous stresses on their knees. Ordinarily, the medial and lateral menisci move as the position of the femur changes. The knee is most stable when it is straight. However, if a locked knee is struck from the side, the lateral meniscus can tear and the supporting ligaments can be seriously damaged. Placing a lot of weight on the knee while it is partially flexed can trap a meniscus between the tibia and femur, resulting in a break or tear in the cartilage. In the most common injury, the lateral surface of the leg is driven medially, tearing the medial meniscus. In addition to being quite painful, the torn cartilage may restrict movement at the joint. It can also lead to chronic problems and the development of a “trick knee”—a knee that feels unstable. Sometimes the meniscus can be heard and felt popping in and out of position when the knee is extended.

Other knee injuries involve tearing one or more stabilizing ligaments or damaging the patella. Torn ligaments can be difficult to correct surgically, and healing is slow. Anterior cruciate ligament (ACL) injuries are frequently caused by twisting an extended weight-bearing knee. Soccer, football, and basketball players are more likely than other athletes to injure their ACLs. Nonsurgical treatment with exercise and braces is possible but requires a

change in activity. Reconstructive surgery using part of the patellar tendon or a graft from a cadaver tendon may allow a return to active sports. A strong hit or force to the lateral surface of the knee, as in a football tackle or flying hockey puck, may damage both the ACL and the medial collateral ligament (MCL).

The patella can be injured in several ways. If the leg is immobilized (as it might be in a football pileup) while trying to extend the knee, the muscles are powerful enough to pull the patella apart. Impacts to the anterior surface of the knee can also shatter the patella.

Knee injuries may lead to chronic painful arthritis that impairs walking. Total knee replacement surgery is rarely performed on young people, but it is becoming increasingly common among older patients with severe arthritis.

The Shoulder Joint

The **shoulder joint**, or *glenohumeral joint*, permits the greatest range of motion of any joint. It is also the most frequently dislocated joint, demonstrating the principle that “stability must be sacrificed to obtain mobility.” The shoulder is a ball-and-socket diarthrosis formed by the articulation of the head of the humerus with the glenoid cavity of the scapula (**Figure 9–9a**).

Joint Capsule and Joint Cavity

The area of the relatively small glenoid cavity is increased by a fibrocartilaginous **glenoid labrum** (*labrum*, lip or edge), which continues beyond the bony rim and deepens the socket (**Figure 9–9a**). The relatively loose joint capsule extends from the scapula, proximal to the glenoid labrum, to the anatomical neck of the humerus. Somewhat oversized, the joint capsule permits an extensive range of motion. The bones of the pectoral girdle provide some stability to the superior surface because the acromion and coracoid process of the scapula project laterally superior to the head of the humerus. However, the surrounding skeletal muscles provide most of the stability at this joint, with help from their associated tendons and various ligaments.

Accessory Structures

The major ligaments that help stabilize the shoulder joint are the *acromioclavicular*, *coracoclavicular*, *coraco-acromial*, *coracohumeral*, and *glenohumeral ligaments* (**Figure 9–9b**). The acromioclavicular ligament reinforces the capsule of the acromioclavicular joint and supports the superior surface of the shoulder. A **shoulder separation** is a relatively common injury involving partial or complete dislocation of the acromioclavicular joint. This injury can result from a hit to the superior surface of the shoulder. The acromion is forcibly depressed while the clavicle is held back by strong muscles. A dislocation of the shoulder joint is different and involves the glenohumeral joint.

The muscles that stabilize the shoulder joint originate on the trunk, pectoral girdle, and humerus and cover the anterior, superior, and posterior surfaces of the capsule. The tendons of the *supraspinatus*, *infraspinatus*, *teres minor*, and *subscapularis muscles* reinforce the joint capsule and limit range of movement. These muscles, known as the muscles of the **rotator cuff**, are the primary structures supporting the shoulder joint and limiting its range of motion (**Figure 9–9b**). Damage to the rotator cuff typically occurs in sports that place severe strains on the shoulder. Whitewater kayakers, baseball pitchers, and quarterbacks are all at high risk for rotator cuff injuries.

Figure 9–9 The Shoulder Joint.

What two bones does the acromioclavicular ligament connect?

Tips

The rotator cuff muscles can be remembered by using the acronym **SITS**, for **s**upraspinatus, **i**nfra-spinatus, **t**eres minor, and **s**ubscapularis.

The anterior, superior, and posterior surfaces of the shoulder joint are reinforced by ligaments, muscles, and tendons, but the inferior capsule is poorly reinforced. As a result, a dislocation caused by an impact or a violent muscle contraction is most likely to occur at this site. Such a dislocation can tear the inferior capsular wall and the glenoid labrum. The healing process typically leaves a weakness that increases the chances for future dislocations.

As at other joints, bursae at the shoulder reduce friction where large muscles and tendons pass across the joint capsule. The shoulder has several important bursae, such as the *subdeltoid bursa*, the *subcoracoid bursa*, the *subacromial bursa*, and the *subscapular bursa* (**Figure 9–9**). A tendon of the biceps brachii muscle runs through the shoulder joint. As it passes through the joint capsule, it is surrounded by a synovial tendon sheath

that is continuous with the joint cavity. Inflammation of any of these extracapsular bursae can restrict motion and produce the painful symptoms of bursitis.

The Hip Joint

The hip joint is a sturdy ball-and-socket diarthrosis that permits flexion, extension, adduction, abduction, circumduction, and rotation. **Figure 9–10** introduces the structure of the hip joint. The acetabulum, a deep fossa in the hip bone, accommodates the head of the femur. Within the acetabulum, articular cartilage extends like a horseshoe to either side of the acetabular notch (**Figure 9–10a**). The *acetabular labrum*, a projecting rim of rubbery fibrocartilage, increases the depth of the joint cavity and helps to seal in synovial fluid.

The joint capsule of the hip joint is extremely dense and strong. It extends from the lateral and inferior surfaces of the hip bone to the intertrochanteric line and intertrochanteric crest of the femur, enclosing both the head and neck of the femur. This arrangement helps to keep the femoral head from moving too far from the acetabulum.

Figure 9–10 The Right Hip Joint.

Four broad ligaments reinforce the joint capsule (**Figure 9–10**). Three of them—the *iliofemoral*, *pubofemoral*, and *ischiofemoral* ligaments—are regional thickenings of the capsule. The *transverse acetabular ligament* crosses the acetabular notch, filling in the gap in the inferior border of the acetabulum. A fifth ligament, the *ligament of the femoral head*, or *ligamentum teres* (*teres*, long and round), originates along the transverse acetabular ligament (**Figure 9–10a**) and attaches to the fovea capitis, a small pit at the center of the femoral head. This ligament tenses only when the hip is flexed and the thigh is undergoing lateral rotation.

Much more important stabilization is provided by the bulk of the surrounding muscles, aided by ligaments and capsular

fibers. The combination of an almost complete bony socket, a strong joint capsule, supporting ligaments, and muscular padding makes the hip joint extremely stable. The head of the femur is well supported, but the ball-and-socket joint is not directly aligned with the weight distribution along the shaft. Stress must be transferred at an angle from the joint, along the thin femoral neck to the length of the femur. *Hip fractures* (fractures of the femoral neck or between the greater and lesser trochanters of the femur) are more common than hip dislocations. As we noted in Chapter 6, femoral fractures at the hip are common in individuals with severe osteoporosis.

Table 9–3 summarizes information about the joints of the appendicular skeleton, the great majority of which are diarthroses.

Table 9–3 Joints of the Appendicular Skeleton

Articulating Bones	Joint	Type of Joint	Movement
JOINTS OF EACH PECTORAL GIRDLE AND UPPER LIMB			
Sternum/clavicle	Sternoclavicular	Plane diarthrosis*	Protraction/retraction, elevation/depression, slight rotation
Scapula/clavicle	Acromioclavicular	Plane diarthrosis	Slight movement
Scapula/humerus	Shoulder, or glenohumeral	Ball-and-socket diarthrosis	Flexion/extension, adduction/abduction, circumduction, rotation
Humerus/ulna and humerus/radius	Elbow (humero-ulnar and humeroradial)	Hinge diarthrosis	Flexion/extension
Radius/ulna	Proximal radio-ulnar	Pivot diarthrosis	Rotation
	Distal radio-ulnar	Pivot diarthrosis	Pronation/supination
Radius/carpal bones	Radiocarpal	Condylar diarthrosis	Flexion/extension, adduction/abduction, circumduction
Carpal bone to carpal bone	Intercarpal	Plane diarthrosis	Slight movement
Carpal bone to metacarpal bone (I)	Carpometacarpal of thumb	Saddle diarthrosis	Flexion/extension, adduction/abduction, circumduction, opposition
Carpal bone to metacarpal bone (II–V)	Carpometacarpal	Plane diarthrosis	Slight flexion/extension, adduction/abduction
Metacarpal bone to phalanx	Metacarpophalangeal	Condylar diarthrosis	Flexion/extension, adduction/abduction, circumduction
Phalanx/phalanx	Interphalangeal	Hinge diarthrosis	Flexion/extension
JOINTS OF THE PELVIC GIRDLE AND LOWER LIMBS			
Sacrum/ilium of hip bone	Sacro-iliac	Plane diarthrosis	Slight movement
Hip bone/hip bone	Pubic symphysis	Amphiarthrosis	None†
Hip bone/femur	Hip	Ball-and-socket diarthrosis	Flexion/extension, adduction/abduction, circumduction, rotation
Femur/tibia	Knee	Complex, functions as hinge	Flexion/extension, limited rotation
Tibia/fibula	Tibiofibular (proximal)	Plane diarthrosis	Slight movement
	Tibiofibular (distal)	Plane diarthrosis and amphiarthrotic syndesmosis	Slight movement
Tibia and fibula with talus	Ankle, or talocrural	Hinge diarthrosis	Flexion/extension (dorsiflexion/plantar flexion)
Tarsal bone to tarsal bone	Intertarsal	Plane diarthrosis	Slight movement
Tarsal bone to metatarsal bone	Tarsometatarsal	Plane diarthrosis	Slight movement
Metatarsal bone to phalanx	Metatarsophalangeal	Condylar diarthrosis	Flexion/extension, adduction/abduction
Phalanx/phalanx	Interphalangeal	Hinge diarthrosis	Flexion/extension

*A “double-plane joint,” with two joint cavities separated by an articular cartilage.

†During pregnancy, hormones weaken the pubic symphysis and permit movement important to childbirth; see Chapter 29.

✓ Checkpoint

- Which tissues or structures provide most of the stability for the shoulder joint?
- Would a tennis player or a jogger be more likely to develop inflammation of the subscapular bursa? Why?
- A football player received a hit to the upper surface of his shoulder, causing a shoulder separation. What does this mean?
- Name the bones making up the shoulder joint.
- At what site are the iliofemoral ligament, pubofemoral ligament, and ischiofemoral ligament located?

See the blue Answers tab at the back of the book.

9-7 With advancing age, arthritis and other degenerative changes often impair joint mobility

Learning Outcome Describe the effects of aging on joints and discuss the most common age-related clinical problems for joints.

Joints are subjected to heavy wear and tear throughout our lifetimes. Problems with joint function are common, especially in older individuals. **Rheumatism** (RŪ-muh-tiz-um) is a general term for pain and stiffness affecting the *musculoskeletal system* (bones, muscles, and joints). **Arthritis** (ar-THRĪ-tis) means *joint inflammation* and encompasses all the rheumatic diseases that affect synovial joints. Many types of arthritis are recognized.

Media resource available for this topic: Practice Anatomy Lab: Skeletal System: Joints

Arthritis always involves damage to the articular cartilages, but the specific cause can vary. For example, arthritis can result from bacterial or viral infection, injury to the joint, decreased viscosity or lack of synovial fluid, metabolic problems, or severe physical stresses. The most common type of arthritis is *osteoarthritis* (os-tē-ō-ar-THRĪ-tis), also known as *degenerative joint disease* (DJD). It generally affects people aged 60 or older. Osteoarthritis can result from cumulative wear and tear at the joint surfaces or from genetic factors affecting collagen formation. In the U.S. population, 25% of women and 15% of men over age 60 show signs of this disease.

Rheumatoid arthritis is an inflammatory condition that affects about 0.5–1.0% of the adult population, generally those between ages 40 and 60, and women more than men. Rheumatoid arthritis occurs when the immune response mistakenly attacks the joint tissues. Such a condition, in which the body attacks its own tissues, is called an *autoimmune disease*. Allergies, bacteria, viruses, and genetic factors have all been proposed as contributing to or triggering the destructive inflammation.

In *gouty arthritis*, crystals of uric acid form within the synovial fluid of joints. The accumulation of uric acid crystals over time eventually interferes with normal movement. This form of arthritis is named after the metabolic disorder known as *gout*, discussed further in Chapter 25. In gout, the crystals are derived from uric acid (a metabolic waste product), and the joint most often affected is the metatarsal–phalangeal joint of the great toe. Gout is relatively rare, but other forms of gouty arthritis are much more common. Some degree of calcium salt deposition occurs in the joints in 30–60% of those over age 85. The cause is unknown, but the condition appears to be linked to age-related changes in the articular cartilages.

Regular exercise, physical therapy, and drugs that reduce inflammation (such as aspirin) can often slow the progress of osteoarthritis. Surgical procedures can realign or redesign the affected joint. In extreme cases involving the hip, knee, elbow, or shoulder, the defective joint can be replaced by an artificial one.

Degenerative changes comparable to those seen in arthritis may result from joint immobilization. When motion ceases, so does the circulation of synovial fluid, and the cartilages begin to degenerate. **Continuous passive motion (CPM)** of any injured joint appears to encourage the repair process by improving the circulation of synovial fluid. A physical therapist or a machine often performs the movement during the recovery process.

With age, bone mass decreases and bones become weaker, so the risk of fractures increases. If osteoporosis develops, the bones may weaken to the point at which fractures occur in response to stresses that could easily be tolerated by normal bones. Hip fractures are among the most dangerous fractures seen in older people, with or without osteoporosis. These fractures, most often involving persons over age 60, may be

accompanied by hip dislocation or pelvic fractures. Although severe hip fractures are most common among those over age 60, in recent years the frequency of hip fractures has increased dramatically among young, healthy professional athletes.

Checkpoint

22. Define rheumatism.
23. Define arthritis.

See the blue Answers tab at the back of the book.

9-8 The skeletal system supports and stores energy and minerals for other body systems

Learning Outcome Explain the functional relationships between the skeletal system and other body systems.

We have discussed the skeletal system in this and the last three chapters. Let's look now at how the bones of the skeletal system function with other body systems. As we discussed in Chapter 6, the living skeleton is dynamic and undergoes continuous remodeling. The balance between osteoblast and osteoclast activity is subject to change. When osteoblast activity predominates, bones thicken and strengthen. When osteoclast activity predominates, bones get thinner and weaker. The balance between bone formation and bone recycling varies with (1) the age of the person, (2) the physical stresses applied to the bone, (3) circulating hormone levels, (4) amounts of calcium and phosphorus absorption and excretion, and (5) genetic or environmental factors. Most of these variables involve some interaction between the skeletal system and other body systems.

In fact, the skeletal system is intimately associated with other systems. For instance, the bones of the skeleton are attachment sites for the muscular system, extensively connected with the cardiovascular and lymphatic systems, and largely under the physiological control of the endocrine system. The digestive and urinary systems also play important roles in providing the calcium and phosphate minerals needed for bone growth. In return, the skeleton represents a reserve of calcium, phosphate, and other minerals that can compensate for reductions in their supply from the diet. Build Your Knowledge **Figure 9-11** reviews the components and functions of the skeletal system and diagrams the major functional relationships between that system and other systems studied so far.

Checkpoint

24. Explain why there must be a balance between osteoclast activity and osteoblast activity.
25. Describe the functional relationship between the skeletal system and the integumentary system.

See the blue Answers tab at the back of the book.

Build Your Knowledge

Figure 9–11 Integration of the SKELETAL system with the other body systems presented so far.

Integumentary System

- The Integumentary System removes excess body heat, synthesizes vitamin D₃ for calcium and phosphate absorption, and protects underlying bones and joints.
- The skeletal system provides structural support for the skin.

Skeletal System

The Skeletal System performs several major functions for the human body. It:

- provides structural support for the body
- stores calcium, phosphate, and other minerals necessary for many functions in other organ systems, and lipids as energy reserves
- produces blood cells and other blood elements in red bone marrow
- protects many soft tissues and organs
- provides leverage for movements generated by skeletal muscles

9 Chapter Review

Study Outline

An Introduction to Joints

1. **Joints**, or **articulations**, exist wherever two bones interconnect.

9-1 Joints are categorized according to their structure or range of motion

2. **Immovable joints** are **synarthroses**; *slightly movable joints* are **amphiarthroses**; and joints that are *freely movable* are called **diarthroses** or synovial joints. (Table 9-1)
3. Alternatively, joints are classified structurally as *fibrous*, *cartilaginous*, *bony*, or *synovial*. (Table 9-1)
4. The four major types of synarthroses are a **suture** (skull bones bound together by dense connective tissue), a **gomphosis** (teeth bound to bony sockets by *periodontal ligaments*), a **synchondrosis** (two bones joined by a rigid cartilaginous bridge), and a **synostosis** (two bones completely fused).
5. The two major types of amphiarthroses are a **syndesmosis** (bones connected by a ligament) and a **symphysis** (bones connected by fibrocartilage).

9-2 Diarthroses: Synovial joints contain synovial fluid and are surrounded by a joint capsule and stabilizing accessory structures

6. The bony surfaces at diarthroses are enclosed within a **joint capsule**, also called an **articular capsule**, that is lined by a synovial membrane.
7. The bony surfaces within a synovial joint are covered by **articular cartilages** and lubricated by **synovial fluid**. Functions of synovial fluid include lubrication, nutrient distribution, and shock absorption.
8. Accessory synovial structures include **menisci**, or *articular discs*; **fat pads**; **accessory ligaments**; **tendons**; and **bursae**. (Figure 9-1)
9. A **dislocation** occurs when articulating surfaces are forced out of position.

9-3 Diarthroses: The different types of synovial joints allow a wide range of skeletal movements

10. The possible types of articular motion are **linear motion** (*plane* or *gliding*), **angular motion**, and **rotation**. (Spotlight Figure 9-2a)
11. Joints are called **monaxial**, **biaxial**, or **triaxial**, depending on the axes of movement they allow. (Spotlight Figure 9-2b)
12. **Plane (gliding) joints** permit limited movement, generally in a single plane. (Spotlight Figure 9-2c)
13. **Hinge joints** are monaxial joints that permit only angular movement in one plane. (Spotlight Figure 9-2c)
14. **Condylar joints** (ellipsoid joints) are biaxial joints with an oval articular face that nestles within a depression in the opposing articular surface. (Spotlight Figure 9-2c)

Media Resources:

- Interactive Physiology
- A&P Flix
- PhysioEx

15. **Saddle joints** are biaxial joints with articular faces that are concave on one axis and convex on the other. (Spotlight Figure 9-2c)
16. **Pivot joints** are monaxial joints that permit only rotation. (Spotlight Figure 9-2c)
17. **Ball-and-socket joints** are triaxial joints that permit rotation as well as other movements. (Spotlight Figure 9-2c)
18. Important terms that describe angular movement are **flexion**, **extension**, **hyperextension**, **abduction**, **adduction**, and **circumduction**. (Figure 9-3)
19. Rotational movement can be **left** or **right**, **medial** (*internal*) or **lateral** (*external*), or, in the bones of the forearm, **pronation** or **supination**. (Figure 9-4)
20. Movements of the foot include **eversion** and **inversion**. The ankle undergoes flexion and extension, also known as **dorsi-flexion** and **plantar flexion**, respectively. (Figure 9-5)
21. **Opposition** is the thumb movement that enables us to grasp objects. **Reposition** is the opposite of opposition. (Figure 9-5)
22. **Retraction** involves moving a structure posteriorly; **protraction** is moving a structure anteriorly. **Depression** and **elevation** occur when we move a structure inferiorly and superiorly, respectively. **Lateral flexion** occurs when the vertebral column bends to one side. (Figure 9-5)

9-4 Intervertebral joints contain intervertebral discs and ligaments that allow for vertebral movements

23. The articular processes of vertebrae form gliding joints with those of adjacent vertebrae. The bodies form symphyses that are separated and cushioned by **intervertebral discs**, which contain an outer **anulus fibrosus** and an inner **nucleus pulposus**. **Vertebral end plates** cover the superior and inferior surfaces of the disc. Several ligaments stabilize the vertebral column. (Figure 9-6; Table 9-2)

9-5 The elbow and knee are both hinge joints

24. The **elbow joint** permits only flexion–extension. It is a hinge diarthrosis whose capsule is reinforced by strong ligaments. (Figure 9-7; Table 9-3)
25. The **knee joint** is a hinge joint made up of three articulations: two formed between the femur and tibia and one between the patella and femur. The joint permits flexion–extension and limited rotation, and it has various supporting ligaments. (Figure 9-8; Table 9-3)

9-6 The shoulder and hip are both ball-and-socket joints

26. The **shoulder joint**, or *glenohumeral joint*, is formed by the glenoid cavity and the head of the humerus. This articulation permits the greatest range of motion of any joint. It is a ball-and-socket diarthrosis with various stabilizing ligaments. Strength and stability are sacrificed in favor of mobility. (Figure 9-9; Table 9-3)
27. The **hip joint** is a ball-and-socket diarthrosis formed between the acetabulum of the hip bone and the head of the femur. The joint permits flexion-extension, adduction-abduction, circumduction, and rotation. Numerous ligaments stabilize the joint. (Figure 9-10; Table 9-3)

9-7 With advancing age, arthritis and other degenerative changes often impair joint mobility

28. Problems with joint function are relatively common, especially in older individuals. **Rheumatism** is a general term for pain and stiffness affecting the musculoskeletal system; several major forms exist. **Arthritis** encompasses all the rheumatic diseases that affect synovial joints. Arthritis becomes increasingly common as we age.

9-8 The skeletal system supports and stores energy and minerals for other body systems

29. Growth and maintenance of the skeletal system are supported by the integumentary system. The skeletal system also interacts with the muscular, cardiovascular, lymphatic, digestive, urinary, and endocrine systems. (Figure 9-11)

Review Questions

See the blue Answers tab at the back of the book.

LEVEL 1 Reviewing Facts and Terms

1. Label the structures in the following illustration of a synovial joint.

- (a) _____ (b) _____
(c) _____ (d) _____
2. A joint that is slightly movable is a(n) (a) synarthrosis, (b) amphiarthrosis, (c) biaxial diarthrosis, (d) monaxial diarthrosis.
3. The joint between adjacent vertebral bodies is a (a) syndesmosis, (b) symphysis, (c) synchondrosis, (d) synostosis.
4. The anterior joint between the two pubic bones is a (a) synchondrosis, (b) synostosis, (c) symphysis, (d) synarthrosis.
5. Joints typically located between the edges of adjacent skull bones are (a) gomphoses, (b) syndesmoses, (c) synchondroses, (d) sutures.
6. The function of the articular cartilage is (a) to reduce friction, (b) to prevent bony surfaces from contacting one another, (c) to provide lubrication, (d) both a and b.
7. Which of the following is *not* a function of synovial fluid? (a) shock absorption, (b) nutrient distribution, (c) maintenance of ionic balance, (d) lubrication of the articular surfaces, (e) waste disposal.
8. The structures that limit the range of motion of a joint and provide mechanical support across or around the joint are (a) bursae, (b) tendons, (c) menisci, (d) all of these.
9. Complete loss of contact between two articulating surfaces is a (a) circumduction, (b) hyperextension, (c) dislocation, (d) supination.
10. The patella is connected to the (a) tibial collateral ligament, (b) fibular collateral ligament, (c) quadriceps tendon, (d) popliteal ligaments.
11. Rotation of the forearm that makes the palm face posteriorly is (a) supination, (b) pronation, (c) proliferation, (d) projection.
12. Movements in the sagittal plane that change the angle between articulating bones are _____ and _____. (a) flexion; extension, (b) abduction; adduction, (c) inversion; eversion, (d) pronation; supination.
13. The atlanto-axial joint is an example of a _____. (a) ball-and-socket joint, (b) saddle joint, (c) hinge joint, (d) pivot joint.
14. Examples of saddle joints, which have complex articular faces, are the (a) carpometacarpal joints of the thumbs, (b) metatarsophalangeal joints, (c) metacarpophalangeal joints 2-5, (d) interphalangeal joints.
15. Movement at the distal radio-ulnar joint is called (a) flexion; extension, (b) pronation; supination, (c) rotation, (d) adduction; abduction, (e) elevation; depression.
16. Movements that occur at the shoulder and the hip represent the actions that occur at a _____ joint. (a) hinge, (b) ball-and-socket, (c) pivot, (d) plane.
17. The annulus fibrosus and nucleus pulposus are structures associated with the (a) intervertebral discs, (b) knee and elbow, (c) shoulder and hip, (d) carpal and tarsal bones.
18. The hip joint is reinforced by the _____ ligament. (a) coracoclavicular, (b) transverse acetabular, (c) popliteal, (d) annular.
19. Although the knee joint is only one joint, it resembles _____ separate joints. (a) two, (b) three, (c) four, (d) five, (e) six.

LEVEL 2 Reviewing Concepts

20. Dislocations involving synovial joints are usually prevented by all of the following *except* (a) structures such as ligaments that stabilize and support the joint, (b) the position of bursae that limits the degree of movement, (c) the presence of other bones that prevent certain movements, (d) the position of muscles and fat pads that limits the degree of movement, (e) the shape of the articular surface.
21. All of the following muscles stabilize the shoulder joint, *except* the (a) supraspinatus muscle, (b) subscapularis muscle, (c) biceps brachii muscle, (d) teres minor muscle.
22. What is the function of the acetabular labrum?
23. Twisting an extended weight-bearing knee frequently leads to the injury of the _____.
24. What happens in joints affected by gouty arthritis?
25. Explain the difference between eversion and inversion.
26. How would you explain the characteristic decrease in height with advancing age?
27. List the muscles of the rotator cuff and explain its function(s).

LEVEL 3 Critical Thinking and Clinical Applications

28. James and Anne rush to the doctor with Mary, their 3-year-old daughter. Mary is in pain, and avoids using her left arm. She holds her arm in flexion and pronation. The parents admit that while playing with Mary in the park, they lifted her up by the wrist. What could have happened to Mary's elbow?

29. Joe injures his knee during a football practice such that the synovial fluid in the knee joint no longer circulates normally. The physician who examines him states that they must reestablish circulation of the synovial fluid before the articular cartilages become damaged. Why?
30. When playing a contact sport, which injury is expected to occur more frequently, a dislocated shoulder or a dislocated hip? Why?

**CLINICAL CASE Wrap-Up What's the Matter with the Birthday Girl?**

Tatiana's mother takes her to the pediatrician. After hearing about Tatiana's symptoms, the pediatrician refers her to a rheumatologist, a doctor who specializes in rheumatic diseases.

Tatiana now has warm, swollen, tender knees with limited motion. The rheumatologist withdraws some synovial fluid from one of her knees using a small needle (a procedure known as *arthrocentesis*). Instead of a small amount of clear, viscous fluid with the consistency of heavy molasses, there is a large amount of thin, cloudy synovial fluid. This fluid cannot do its important jobs of joint lubrication, nutrient distribution, and shock absorption.

The doctor says that Tatiana has juvenile rheumatoid arthritis, the most common type of childhood arthritis. Unlike the

more common osteoarthritis found in older populations, rheumatoid arthritis is an autoimmune, inflammatory disease of the synovial membrane seen in people of all ages. For unknown reasons, the immune system mistakenly attacks the synovial membrane, causing it to grow abnormally and produce large amounts of unhealthy synovial fluid. Tatiana may outgrow her joint disease, or the synovitis may destroy her joint cartilage.

1. What category of joints is likely to be affected by juvenile rheumatoid arthritis?
2. If you could look inside Tatiana's knee joint, what do you think the synovial membrane would look like?

See the blue Answers tab at the back of the book.

Related Clinical Terms

ankylosing spondylitis: A chronic, progressive inflammatory disease of the intervertebral spaces that causes abnormal fusion of the vertebrae.

arthroplasty: The surgical reconstruction or creation of an artificial joint.

arthroscopy: Insertion of a narrow tube containing optical fibers and a tiny camera (arthroscope) directly into the joint for visual examination.

Bouchard nodes: Bony enlargements on the proximal interphalangeal joints due to osteoarthritis.

chondromalacia: Softening of cartilage that results from strenuous activity or an overuse injury.

Heberden nodes: Bony overgrowths on the distal interphalangeal joints due to osteoarthritis that cause the patient to have knobby fingers.

joint mice: Small fibrous, cartilaginous, or bony loose bodies in the synovial cavity of a joint.

Lyme disease: An infectious disease transmitted to humans from the bite of a tick infected with *Borrelia burgdorferi* bacteria or *Borrelia mayonii* bacteria, causing flu-like symptoms and joint pain.

pannus: Granulation tissue (combination of fibrous connective tissue and capillaries) forming within a synovial membrane, which releases cartilage-destroying enzymes.

prepatellar bursitis: Inflammation of the bursa over the front of the knee just above the kneecap; also known as housemaid's knee.

prosthesis: An artificial substitute for a body part.

synovitis: Inflammation of the synovial membrane.

tophi: Deposits of uric acid crystals often found around joints and usually associated with gout.

Muscle Tissue

Learning Outcomes

These Learning Outcomes correspond by number to this chapter's sections and indicate what you should be able to do after completing the chapter.

- 10-1 ■ Identify the common properties of muscle tissue and the primary functions of skeletal muscle.
- 10-2 ■ Describe the organization of muscle at the tissue level.
- 10-3 ■ Describe the characteristics of skeletal muscle fibers and identify the components of a sarcomere.
- 10-4 ■ Identify the components of the neuromuscular junction, and summarize the events involved in the neural control of skeletal muscle contraction and relaxation.
- 10-5 ■ Describe the mechanism responsible for the different amounts of tension produced in a muscle fiber.
- 10-6 ■ Compare the different types of skeletal muscle contraction.
- 10-7 ■ Describe the mechanisms by which muscle fibers obtain the energy to power contractions.
- 10-8 ■ Relate the types of muscle fibers to muscle performance, discuss muscle hypertrophy, atrophy, and aging, and describe how physical conditioning affects muscle tissue.
- 10-9 ■ Identify the structural and functional differences between skeletal muscle fibers and cardiac muscle cells.
- 10-10 ■ Identify the structural and functional differences between skeletal muscle fibers and smooth muscle cells and discuss the roles of smooth muscle tissue in systems throughout the body.

CLINICAL CASE Keep on Keepin' on

Rhetta has been drumming in an all-girl band for 5 years. At their last gig 2 weeks ago, the crowd went wild. The band played an encore and she gave it her all. Afterward, she could barely hang onto her drumsticks. This was not the first time that her arms had “wimped out,” but it was the worst time. It seems that lately, she can play well for the first few songs, but then she completely loses her strength. This week, she had trouble swallowing. She also complains of having double vision. Her eyelids droop, especially when she wakes up. She feels like a mess. Her band members have encouraged her to see a doctor, and now she’s ready to make it happen.

Rhetta sees a neurologist who takes a complete medical history and does a thorough physical exam. She realizes how

weak her legs have gotten when he asks her to stand up from her chair without using her arms. Walking on tiptoes is impossible for her. When the doctor lifts her eyelids, she’s not able to track his finger with her gaze, and she still sees double.

“I would like to perform a test,” says the neurologist, starting an IV. He injects a small amount of a drug. Suddenly, Rhetta’s strength returns. She opens both eyes wide and is no longer seeing double. She can toe walk, heel walk, and get up unassisted many times in a row. She feels like she could play her drums all night. But after 30 minutes, her weakness returns. **What is going on with Rhetta? To find out, turn to the Clinical Case Wrap-Up at the end of the chapter.**

An Introduction to Muscle Tissue

In this chapter we discuss muscle tissue, one of the four primary tissue types. As we introduced in Chapter 4, our bodies contain three types of muscle tissue: (1) *skeletal muscle*, (2) *cardiac muscle*, and (3) *smooth muscle*. In this chapter we pay particular attention to skeletal muscle tissue. We examine the structural and physiological characteristics of skeletal muscle cells and relate those features to the functions of the entire tissue. We conclude the chapter with an overview of the differences among skeletal, cardiac, and smooth muscle tissues. Studying this chapter will prepare you for our discussion of the muscular system in Chapter 11.

10-1 The primary function of muscle tissue is to produce movement

Learning Outcome Identify the common properties of muscle tissue and the primary functions of skeletal muscle.

Muscle tissue consists chiefly of muscle cells that are highly specialized for contraction. This contraction at the cellular level produces many types of movement in the body. Without these muscle tissues, nothing in the body would move, and the body itself could not move. Skeletal muscle tissue moves the body by pulling on our bones, making it possible to walk, dance, bite an apple, or play the guitar. Cardiac muscle tissue pumps blood through the cardiovascular system. Smooth muscle tissue pushes fluids and solids along the digestive tract and other internal organs and regulates the diameters of small arteries and respiratory passageways (bronchioles).

Common Properties of Muscle Tissue

Muscle tissue shares these four common properties: excitability, contractility, extensibility, and elasticity. **Excitability**, also

known as responsiveness or irritability, is the ability to receive and respond to a stimulus. Muscle tissue responds to a chemical stimulus from a nerve cell with a change in membrane potential. **Contractility** refers to the ability of a muscle cell to shorten when it is stimulated. **Extensibility** is stretching movement of a muscle, while **elasticity** is the ability of a muscle to recoil (spring back) to its resting length.

Functions of Skeletal Muscle

Skeletal muscles have the following functions:

- **Producing Movement.** In general, skeletal muscle contractions pull on tendons to move our bones. Skeletal muscle actions range from simple motions, such as extending the arm or breathing, to the highly coordinated movements of swimming or piano playing.
- **Maintaining Posture and Body Position.** Tension in skeletal muscles maintains body posture—for example, holding the head still and balancing body weight above the feet when walking. Without constant muscular activity, neither sitting upright nor standing would be possible.
- **Supporting Soft Tissues.** Layers of skeletal muscle make up the abdominal wall and the pelvic floor cavity. These muscles support the weight of our visceral organs and shield our internal tissues from injury.
- **Guarding Body Entrances and Exits.** Skeletal muscles called sphincters (SFINK-terz) encircle the openings of the digestive and urinary tracts. These muscles provide voluntary control over swallowing, defecating, and urinating. (Involuntary sphincters also have smooth muscle.)
- **Maintaining Body Temperature.** Muscle contractions use energy, and whenever energy is used in the body, some of it

is converted to heat. The heat released by working muscles keeps body temperature in the range needed for normal functioning.

- **Storing Nutrients.** When our diet contains too few proteins or calories, the contractile proteins in skeletal muscles are broken down, and their amino acids released into the circulation. The liver can use some of these amino acids to synthesize glucose, and others can be broken down to provide energy.

Let's now turn to the functional anatomy of a typical skeletal muscle.

✓ Checkpoint

1. Identify the three types of muscle tissue and cite their major functions.
2. Identify the common properties shared by muscle tissues.
3. Identify the primary functions of skeletal muscle.

See the blue Answers tab at the back of the book.

10-2 Skeletal muscle contains muscle tissue, connective tissues, blood vessels, and nerves

Learning Outcome Describe the organization of muscle at the tissue level.

Figure 10-1 illustrates the organization of a representative skeletal muscle. **Skeletal muscles** are organs composed mainly of skeletal muscle tissue, but they also contain connective tissues, blood vessels, and nerves. Each cell in skeletal muscle tissue is a single muscle *fiber*. Skeletal muscles attach directly or indirectly to bones.

Here we examine how muscle tissue is organized in a skeletal muscle by connective tissues, and how skeletal muscles are supplied with blood vessels and nerves.

Organization of Connective Tissues and Muscle Tissue

As shown in **Figure 10-1a**, the muscle tissue in a skeletal muscle is surrounded by three layers of connective tissue: (1) an epimysium, (2) a perimysium, and (3) an endomysium.

The **epimysium** (ep-i-MIZ-ē-um; *epi-*, on + *mys*, muscle) is a dense layer of collagen fibers that surrounds the entire muscle. It separates the muscle from nearby tissues and organs. The epimysium is connected to the deep *fascia* (FASH-ē-uh), a dense connective tissue layer.

The **perimysium** (per-i-MIZ-ē-um; *peri-*, around) divides the skeletal muscle into a series of compartments. Each compartment contains a bundle of muscle fibers called a **fascicle** (FAS-i-kl; *fasciculus*, a bundle; **Figure 10-1b**). The perimysium contains collagen and elastic fibers as well as the blood vessels and nerves that supply the muscle fibers within the fascicles.

Within a fascicle, the delicate connective tissue of the **endomysium** (en-dō-MIZ-ē-um; *endo-*, inside) surrounds the individual skeletal muscle cells, called *muscle fibers* (**Figure 10-1c**), and loosely interconnects adjacent muscle fibers. This flexible, elastic connective tissue layer contains (1) *capillary networks* (the smallest blood vessels) that supply blood to the muscle fibers, (2) **myosatellite cells**, stem cells that help repair damaged muscle tissue, and (3) nerve fibers that control the muscle. All these structures are in direct contact with the individual muscle fibers.

The collagen fibers of the perimysium and endomysium are interwoven and blend into one another. At each end of the muscle, the collagen fibers of the epimysium, perimysium, and endomysium come together to form either a bundle known as a **tendon** or a broad sheet called an **aponeurosis** (ap-ō-nū-RŌ-sis). Tendons and aponeuroses usually attach skeletal muscles to bones. Where they contact the bone, the collagen fibers extend into the bone matrix, providing a firm attachment. Thus, any contraction of the muscle pulls on the attached bone.

Function of Skeletal Muscle Components

As we have seen, the connective tissues of the endomysium and perimysium contain the blood vessels and nerves that supply the muscle fibers. Muscle contraction requires tremendous quantities of energy. An extensive vascular network delivers the necessary oxygen and nutrients and carries away the metabolic wastes generated by active skeletal muscles. The blood vessels and the nerves generally enter the muscle together and follow the same branching course through the perimysium. Each fascicle receives branches of these blood vessels and nerves. Within the endomysium, arterioles (small arteries) supply blood to a capillary network that services the individual muscle fiber.

Skeletal muscles contract only when the central nervous system stimulates them. Axons, *nerve fibers* extending from neurons, penetrate the epimysium, branch through the perimysium, and enter the endomysium to innervate individual muscle fibers. Skeletal muscles are often called voluntary muscles because their contractions are consciously controlled. We may also control many skeletal muscles at a subconscious level. For example, skeletal muscles involved with breathing, such as the *diaphragm* (DĪ-a-fram), usually work outside our conscious awareness.

Next, let's examine the microscopic structure of a typical skeletal muscle fiber and relate that microstructure to the physiology of the contraction process.

✓ Checkpoint

4. Describe the three connective tissue layers associated with skeletal muscle tissue.
5. How would severing the tendon attached to a muscle affect the muscle's ability to move a body part?

See the blue Answers tab at the back of the book.

Figure 10–1 The Organization of Skeletal Muscles. A skeletal muscle consists of fascicles (bundles of muscle fibers) enclosed by the epimysium. The bundles are separated by connective tissue fibers of the perimysium, and within each bundle, each of the muscle fibers is surrounded by an endomysium. Each muscle fiber has many superficial nuclei, as well as mitochondria and other organelles.

10-3 Skeletal muscle fibers are organized into repeating functional units that contain sliding filaments

Learning Outcome Describe the characteristics of skeletal muscle fibers and identify the components of a sarcomere.

Skeletal muscle fibers are quite different from the “typical” cells we described in Chapter 3. One obvious difference is size: Compared to other cells, skeletal muscle fibers are enormous. A muscle fiber from a thigh muscle could have a diameter of $100\ \mu\text{m}$ ($0.1\ \text{mm}$) and a length up to $30\ \text{cm}$ ($12\ \text{in.}$). Another major difference is that skeletal muscle fibers are *multinucleate*: Each contains hundreds of nuclei just internal to the plasma membrane. The genes in these nuclei control the production of enzymes and structural

proteins required for normal muscle contraction. The more copies of these genes, the faster these proteins can be produced.

The distinctive features of size and multiple nuclei are related. During development, groups of embryonic cells called **myoblasts** (*myo-*, muscle + *blastos*, formative cell) fuse, forming individual multinucleate skeletal muscle fibers (**Figure 10–2a**). Each nucleus in a skeletal muscle fiber reflects the contribution of a single myoblast. Some myoblasts do not fuse with developing muscle fibers. These unfused cells remain in adult skeletal muscle tissue as the myosatellite cells seen in **Figures 10–1c** and **10–2a**.

Figure 10–2 The Formation of a Multinucleate Skeletal Muscle Fiber.

After an injury, myosatellite cells may enlarge, divide, and fuse with damaged muscle fibers, thereby assisting in the repair of the tissue.

A final way that skeletal muscle fibers are different from other cells is that they are banded, or *striated*. These striations are visible with a light microscope, so skeletal muscle tissue is also known as **striated muscle**. Each muscle fiber contains hundreds to thousands of cylindrical structures called *myofibrils* (Figure 10–2b). As we will see, the striations are due to the precise arrangements of *thin* (*actin*) and *thick* (*myosin*) filaments in these myofibrils. The arrangement of these filaments forms the repeating functional unit called a *sarcomere*; the sliding of these filaments allows a muscle fiber to contract. In addition, the fiber contains other unique components that support the function of the sarcomeres. Let's examine these components.

The Sarcolemma and Transverse Tubules

The **sarcolemma** (sar-kō-LEM-uh; *sarkos*, flesh + *lemma*, husk), or plasma membrane of a muscle fiber, surrounds the **sarcoplasm**

(SAR-kō-plazm), or cytoplasm of the muscle fiber (Figure 10–3). Like the plasma membranes of other body cells, the sarcolemma has a characteristic membrane potential. In a skeletal muscle fiber, a sudden change in the membrane potential is the first step that leads to a contraction.

Even though a skeletal muscle fiber is very large, all regions of the cell must contract at the same time. For this reason, the signal to contract must be sent and distributed quickly throughout the interior of the cell. This signal is propagated through the transverse tubules. **Transverse tubules**, or **T tubules**, are narrow tubes whose surfaces are continuous with the sarcolemma and extend deep into the sarcoplasm (Figure 10–3). They are filled with extracellular fluid and form passageways through the muscle fiber, like a network of tunnels through a mountain. As extensions of the sarcolemma, T tubules share the same special property of being able to propagate an electrical impulse. As a result, electrical impulses generated by the sarcolemma also travel along the T tubules into the cell interior. These impulses, called *action potentials*, trigger muscle fiber contraction.

Figure 10–3 The Structure and Internal Organization of a Skeletal Muscle Fiber.

The terminal cisternae that form a triad along with a T tubule are part of what organelle?

The Sarcoplasmic Reticulum

In skeletal muscle fibers, a membrane complex called the **sarcoplasmic reticulum (SR)** forms a tubular network around each myofibril, fitting over it like lacy shirtsleeves (**Figure 10–3**). The SR is similar to the smooth endoplasmic reticulum of other cells.

Wherever a T tubule encircles a myofibril, the tubule is tightly bound to the membranes of the SR. On either side of a T tubule, the tubules of the SR enlarge, fuse, and form expanded chambers called **terminal cisternae** (sis-TUR-nē). This combination of a pair of terminal cisternae plus a T tubule is known as a **triad**. Although the membranes of the triad are tightly bound together, their fluid contents are separate and distinct.

The SR is specialized for the storage and release of calcium ions. In Chapter 3, we noted that special ion pumps keep the intracellular concentration of calcium ions (Ca^{2+}) very low. Most cells pump calcium ions out across their plasma membranes and

into the extracellular fluid. Although skeletal muscle fibers do export Ca^{2+} in this way, they also remove calcium ions from the cytosol by actively transporting them into the terminal cisternae of the SR. The cytosol of a resting skeletal muscle fiber contains a very low concentration of Ca^{2+} , around 10^{-7} mmol/L. The free Ca^{2+} concentration level inside the terminal cisternae may be as much as 1000 times higher. In addition, terminal cisternae contain the protein *calsequestrin*, which reversibly binds Ca^{2+} . Including both the free calcium and the bound calcium, the total concentration of Ca^{2+} inside terminal cisternae can be 40,000 times greater than the surrounding cytosol.

Myofibrils

A **myofibril** is 1–2 μm in diameter and as long as the entire muscle fiber. Branches of the T tubules and the sarcoplasmic reticulum encircle each myofibril. The active shortening of myofibrils is responsible for skeletal muscle fiber contraction.

Figure 10–4 Sarcomere Structure, Longitudinal Views.

Myofibrils consist of bundles of protein filaments called **myofilaments**. Myofibrils contain two types of myofilaments that we introduced in Chapter 3: *thin filaments* composed primarily of *actin* and *thick filaments* composed primarily of *myosin*. In addition, myofibrils contain *titin*, elastic myofilaments associated with the thick filaments. (We consider the role of titin later in the chapter.)

Myofibrils are anchored to the inner surface of the sarcolemma at each end of a skeletal muscle fiber. In turn, the outer surface of the sarcolemma is attached to collagen fibers of the tendon or aponeurosis of the skeletal muscle. As a result, when the myofibrils shorten or contract, the entire cell shortens and pulls on the tendon.

Scattered among the myofibrils are mitochondria and granules of glycogen, the storage form of glucose. Mitochondrial activity and

glucose breakdown by glycolysis provide energy in the form of ATP for short-duration, maximum-intensity muscular contractions.

Sarcomeres

As we have discussed, thin and thick myofilaments are organized into repeating structural and functional units called **sarcomeres** (SAR-kō-mērz; *sarkos*, flesh + *meros*, part) (Figure 10–4). Sarcomeres are the smallest contractile units of the muscle fiber. Interactions between the thick and thin filaments within sarcomeres are responsible for muscle contraction.

A myofibril consists of approximately 10,000 sarcomeres, end to end. Each sarcomere has a resting length of about 2 μm . A sarcomere contains (1) thick filaments, (2) thin filaments, (3) proteins that stabilize the positions of the thick and thin filaments, and (4) proteins that regulate the interactions

Figure 10-5 Sarcomere Structure, Superficial and Cross-Sectional Views.

between thick and thin filaments. Let's look at these components, including how their arrangement produces the characteristic banding of myofibrils and the sarcomeres they contain.

Bands of the Sarcomere

Differences in the size, density, and distribution of thick filaments and thin filaments account for the banded appearance of each myofibril (**Figure 10-4**). Each sarcomere has dark bands called **A bands** and light bands called **I bands**. The names of these bands are derived from *anisotropic* and *isotropic*, which refer to their appearance when viewed using polarized light microscopy.

Tips

You can remember that actin occurs in thin filaments by associating the "tin" in **actin** with the word *thin*. Then remember that thin filaments look light and form the **I** band. Similarly, the **A** bands are dark.

The A Band. The A bands contain regions of overlapping thick (myosin) and thin (actin) filaments. The thick filaments are at the center of each sarcomere, in the A band. The A band is about as long as a typical thick filament. The A band also

includes portions of thin filaments and contains these three subdivisions (**Figure 10-4**):

- **The M Line.** The **M line** is in the center of the A band. (The M is for *middle*.) Proteins of the M line connect the central portion of each thick filament to neighboring thick filaments. These dark-staining proteins help stabilize the positions of the thick filaments.
- **The H Band.** In a resting sarcomere, the **H band** is a lighter region on either side of the M line. The H band contains thick filaments, but no thin filaments.
- **The Zone of Overlap.** The **zone of overlap** is a dark region where thin filaments are located between the thick filaments. Here three thick filaments surround each thin filament, and six thin filaments surround each thick filament.

The longitudinal views in **Figure 10-4** and the cross-sectional views in **Figure 10-5** should help you to visualize a three-dimensional image of these regions of a sarcomere.

Two T tubules encircle each sarcomere, and the triads containing them are in the zones of overlap, at the edges of the A band (**Figure 10-3**). As a result, calcium ions released by the SR enter the regions where thick and thin filaments can interact.

The I Band. The I band is a region of the sarcomere that contains thin filaments but no thick filaments. It extends from the A band of one sarcomere to the A band of the next sarcomere (Figure 10-4). Z lines bisect the I bands and mark the boundary between adjacent sarcomeres. The Z lines consist of proteins called *actinins*, which interconnect thin filaments of adjacent sarcomeres. At both ends of the sarcomere, thin filaments extend from the Z lines toward the M line and into the zone of overlap.

Strands of the elastic protein **titin** extend from the tips of the thick filaments to attachment sites at the Z line (Figures 10-4a, 10-5). Titin helps keep the thick and thin filaments in proper alignment and aids in restoring resting sarcomere length after contraction. It also helps the muscle fiber resist extreme stretching that would otherwise disrupt the contraction mechanism.

Each Z line is surrounded by a meshwork of intermediate filaments that interconnect adjacent myofibrils. The myofibrils closest to the sarcolemma, in turn, are bound to attachment sites on the interior surface of the membrane. Because the Z lines of all the myofibrils are aligned in this way, the alternating A bands and I bands form the banded appearance of the muscle fiber (Figure 10-2b).

Figure 10-6 reviews the levels of skeletal muscle organization we have discussed so far.

Myofilaments

Now let's consider the molecular structure of the thin and thick myofilaments responsible for muscle contraction.

Thin Filaments. A typical **thin filament** is 5–6 nm in diameter and is 1 μm long (Figure 10-7a). A single thin filament contains four main proteins: F-actin, nebulin, tropomyosin, and troponin (Figure 10-7b).

Filamentous actin, or **F-actin**, is a twisted strand composed of two rows of 300–400 individual globular molecules (monomers) of **G-actin** (Figure 10-7b). A long strand of **nebulin** extends along the F-actin strand in the cleft between the rows of G-actin molecules. Nebulin holds the F-actin strand together. Each G-actin molecule contains an **active site**, where myosin (in the thick filaments) can bind. This is similar to enzymatic reactions in which a substrate molecule binds to the active site of an enzyme. (Recall that a substrate is a substance that is acted on by an enzyme.)

Under resting conditions, however, the **tropomyosin** complex prevents myosin binding. Strands of **tropomyosin** ($\text{tr}\bar{\text{O}}\text{-p}\bar{\text{O}}\text{-M}\bar{\text{I}}\text{-}\bar{\text{O}}\text{-sin}$; *trope*, turning) cover the active sites on G-actin and prevent actin–myosin interaction. A tropomyosin molecule is a double-stranded protein that covers seven active sites. It is bound to one molecule of troponin midway along its length. A **troponin** ($\text{TR}\bar{\text{O}}\text{-p}\bar{\text{O}}\text{-nin}$) molecule consists of three globular subunits. One subunit binds to tropomyosin, locking them

Figure 10-6 Levels of Functional Organization in a Skeletal Muscle.

Match the level of organization with the structure that surrounds it: *level of organization*: skeletal muscle, muscle fascicle, muscle fiber, myofibril; *surrounding structure*: endomysium, epimysium, perimysium, sarcoplasmic reticulum.

Figure 10-7 Thin and Thick Filaments.

together as a troponin-tropomyosin complex, and a second subunit binds to one G-actin, holding the troponin-tropomyosin complex in position. The third subunit has a receptor that binds two calcium ions. In a resting muscle, the intracellular Ca^{2+} concentration is very low, and that binding site is empty.

A contraction can occur only when the troponin-tropomyosin complex changes position, exposing the active sites on actin. The change in position takes place when calcium ions bind to their receptors on the troponin molecules.

The thin filaments are attached to the Z lines at either end of the sarcomere (**Figure 10-7a**). Although it is called a “line” because it looks like a dark line on the surface of the myofibril under a microscope, the Z line appears as a zigzag line in sectional view and is more like a disc with a waffle surface (**Figure 10-5b**). For this reason, the Z line is often called the *Z disc*.

Thick Filaments. **Thick filaments** are 10–12 nm in diameter and 1.6 μm long (**Figure 10-7c**). A thick filament contains

about 300 **myosin** molecules, each made up of a pair of myosin subunits twisted around one another (**Figure 10-7d**). The long tail is bound to other myosin molecules in the thick filament. The free head, which projects outward toward the nearest thin filament, has two globular protein subunits.

All the myosin molecules are arranged with their tails pointing toward the M line (**Figure 10-7c**). The H band includes a central region where there are no myosin heads. Elsewhere on the thick filaments, the myosin heads are arranged in a spiral, each facing one of the surrounding thin filaments.

Each thick filament has a core of titin. On either side of the M line, a strand of titin extends the length of the thick filament and then continues across the I band to the Z line on that side. Titin has been described as a “molecular spring.” Titin has *elastic* properties, which means that it will recoil after stretching. In the normal resting sarcomere, the titin strands are completely relaxed. They become tense only when some external force stretches the sarcomere.

Figure 10–8 Changes in the Appearance of a Sarcomere during the Contraction of a Skeletal Muscle Fiber.

The Sliding-Filament Theory of Muscle Contraction

What happens to a sarcomere when a skeletal muscle fiber contracts? As shown in **Figure 10–8**, (1) the H bands and I bands of the sarcomeres narrow, (2) the zones of overlap widen, (3) the Z lines move closer together, and (4) the width of the A band remains constant. These observations make sense only if the thin filaments are sliding toward the center of each sarcomere, alongside the thick filaments. This explanation is known as the **sliding-filament theory**. The contraction weakens with the disappearance of the I bands, at which point the Z lines are in contact with the ends of the thick filaments.

During a contraction, sliding occurs in every sarcomere along the myofibril. As a result, the myofibril gets shorter. Because myofibrils are attached to the sarcolemma at each Z line and at either end of the muscle fiber, when myofibrils get shorter, so does the muscle fiber.

Tips

To better understand the actions of sliding filaments during a muscle contraction, imagine someone holding their hands in front of their chest, palms toward their body and thumbs sticking straight up. The person then moves their hands together, so that the fingers of one hand move in between the fingers of the other hand. Their fingers represent thin and thick filaments, and their thumbs represent the Z lines. The result is that their finger length stays the same, but their thumbs move closer together.

If neither end of the myofibril is held in position, both ends move toward the middle, as seen in **Figure 10–9a**. Such a contraction seldom occurs in an intact skeletal muscle, because one end of the muscle (the *origin*) is usually fixed in position during a contraction, while the other end (the *insertion*) moves. In that case, the free end moves toward the fixed end (**Figure 10–9b**). As the muscle fiber contracts, it pulls on the

Figure 10–9 Shortening during a Contraction.

10

tendon's collagen fibers, which are embedded in the bone. This pulling on the tendon ultimately causes bone movement.

If neither end of the myofibril can move, thick and thin filament interactions consume energy and generate tension, but sliding cannot occur. We discuss this kind of contraction in a later section.

10-4 Motor neurons stimulate skeletal muscle fibers to contract at the neuromuscular junction

Learning Outcome Identify the components of the neuromuscular junction, and summarize the events involved in the neural control of skeletal muscle contraction and relaxation.

We have learned that myofilaments in a sarcomere change position during a contraction, but not *how* these changes occur. In this section we first discuss how the plasma membranes of neurons and skeletal muscle fibers propagate electrical impulses. (This topic is explored more fully in Chapter 12.) We then look at how skeletal muscle activity is under neural control (as shown in **Spotlight Figure 10–10**), how neural stimulation of a muscle fiber is coupled to the contraction of the fiber (presented in **Spotlight Figure 10–11**), and how actin and myosin interact to cause sarcomere contraction (shown in **Spotlight Figure 10–12**). Read the following text about excitable membranes before studying these three Spotlight figures.

Electrical Impulses and Excitable Membranes

As we learned in Chapter 3, all the cells of the body maintain a membrane potential due to an unequal distribution of

positive and negative charges across their plasma membrane. The unequal charge distribution means cells are *polarized*, much like miniature batteries. In cells, the inner surface of the plasma membrane is slightly negative compared to the outer surface. The membrane potential is a measure of cellular polarization (in millivolt units) that compares the cytoplasmic membrane surface charge to the extracellular membrane surface charge. In unstimulated (resting) neurons and skeletal muscle fibers, typical resting membrane potentials are -70 mV and -85 mV, respectively.

Recall that the main contributors of negative charges within a cell are proteins that cannot cross the plasma membrane. There is also an excess of sodium ions outside a cell and an excess of potassium ions inside a cell. These ions can cross a membrane through membrane channels that are specific for each ion, or they can cross by using ion pumps.

Various stimuli can lead to a temporary change in the distribution of electrical charges across the plasma membranes of all body cells. Differences in sodium ion and potassium ion membrane permeability underlie such changes. An influx of sodium ions leads to *depolarization* as the membrane potential becomes less negative. The movement of potassium ions out of a cell leads to *hyperpolarization* as the membrane potential becomes more negative. A return to the resting potential is called *repolarization*. In most cells, the depolarization or hyperpolarization of a plasma membrane is a localized change limited by the presence or absence of stimulation. Called a *graded potential*, it does not continue to spread over the plasma membrane.

Neurons and skeletal muscle fibers, however, have electrically **excitable membranes**. Excitable membranes permit rapid communication between different parts of a cell. In neurons and skeletal muscle fibers, the depolarization and repolarization events produce an electrical impulse, or **action potential**, that is propagated along their plasma membranes. Unlike the plasma membranes of most cells, excitable membranes contain *voltage-gated ion channels* that are activated and inactivated by changes in the membrane potential. These electrical channels become activated when the membranes of neurons and skeletal muscle fibers first depolarize from the resting potential to a *threshold potential* (from -70 to -60 mV for neurons and from -85 to -55 mV for skeletal muscle fibers). Upon reaching the threshold potential, *voltage-gated sodium ion channels* open and there is a rapid influx of positively charged sodium ions into the cell.

The inside of the membrane reverses from a negative to a positive charge, and the depolarization peaks at a membrane potential of $+30$ mV with the closure of the voltage-gated sodium ion channels. *Repolarization* of the membrane then begins as voltage-gated potassium ion channels open and positively charged potassium ions leave the cell. The loss of more positive charges than entered the cell causes the membrane

potential to become negative again. A “resting” *refractory period* follows, and the former concentrations of sodium and potassium ions across the plasma membrane are restored through the action of sodium–potassium ion pumps. A further depolarization cannot occur until the refractory period is over. As a result, the action potential travels in one direction because the refractory period prevents it from propagating back in the direction from which it was initiated.

The Control of Skeletal Muscle Activity

Skeletal muscle fibers cannot begin contraction until they receive instructions from *motor neurons* of the central nervous system (brain and spinal cord). The motor neurons carry the instructions in the form of action potentials. A contraction begins when the sarcoplasmic reticulum releases stored calcium ions (Ca^{2+}) into the cytosol of the muscle fiber. That release is under the control of the nervous system. As the intracellular calcium ions are reabsorbed, the contraction ends and muscle relaxation occurs. This next section details the events that lead up to contraction and then cause relaxation.

Events at the Neuromuscular Junction

Communication between a neuron and another cell occurs at a *synapse*. When the other cell is a skeletal muscle fiber, the synapse is known as a **neuromuscular junction (NMJ)**. The NMJ is made up of an *axon terminal* (synaptic terminal) of a neuron, a specialized region of the sarcolemma called the *motor end plate*, and, in between, a narrow space called the *synaptic cleft*.

A motor neuron stimulates a muscle fiber through the series of steps shown in **Spotlight Figure 10–10**. In this process, the axon terminal of a neuron releases a chemical signal called a **neurotransmitter** into the synaptic cleft. This signal is *acetylcholine*, or *ACh*. ACh binds to an ACh receptor membrane channel on the *motor end plate* of the muscle fiber. The ACh receptor is a *chemically gated Na^+ channel*. ACh binding opens the channel, which allows Na^+ to enter the cell. The inflow of positive charges depolarizes the motor end plate and generates an action potential that sweeps across the sarcolemma. Make sure to study **Spotlight Figure 10–10** before reading on.

Excitation–Contraction Coupling

The link between the generation of an action potential in the sarcolemma and the start of a muscle contraction is called **excitation–contraction coupling**. This coupling occurs at the triads. On reaching a triad, an action potential triggers the release of Ca^{2+} from the terminal cisternae of the sarcoplasmic reticulum. The change in the permeability of the SR to Ca^{2+} is temporary, lasting only about 0.03 seconds. Yet within a millisecond, the Ca^{2+} concentration in and around the sarcomere reaches 100 times its resting level. Because the terminal cisternae are located at the zones of overlap, where the thick and

thin filaments interact, the effect of calcium ion release on the sarcomere is almost instantaneous.

Troponin is the lock that keeps the active sites inaccessible; calcium ions are the key to that lock. Recall from **Figure 10–7b** that troponin binds to both actin and tropomyosin, and that the tropomyosin molecules cover the active sites and prevent interactions between thick filaments and thin filaments. Each troponin molecule also has a binding site for calcium ions, and this site is empty when the muscle fiber is at rest. Calcium ion binding changes the shape of the troponin molecule and weakens the bond between troponin and actin. The troponin molecule then changes position, rolling the attached tropomyosin strand away from the active sites (**Spotlight Figure 10–11**). With this change, the *contraction cycle* begins.

The Contraction Cycle and Generation of Muscle Tension

The **contraction cycle** is a series of molecular events that enable muscle contraction. After the active sites are exposed, the myosin heads bind to them, forming **cross-bridges**. The connection between the head and the tail functions as a hinge that lets the head pivot. When it pivots, using the energy released from the hydrolysis of ATP, the head swings toward the M line, a movement known as the **power stroke**. This pivoting is the key step in muscle contraction. **Spotlight Figure 10–12** shows the interlocking steps of the contraction cycle.

When muscle cells contract, they pull on the attached tendon fibers the way a line of people might pull on a rope. Let’s consider what is happening by applying some basic physical principles to muscle cells. The pull, called *tension*, is an active force: Energy must be expended to produce it. Tension is applied to some object, whether a rope, a rubber band, or a book on a tabletop. Tension applied to an object tends to pull the object toward the source of the tension. However, before movement can occur, the applied tension must overcome the object’s *load* (or *resistance*), a passive force that opposes movement. The amount of load can depend on the weight of the object, its shape, friction, and other factors. When the applied tension exceeds the load, the object moves.

In contrast, *compression*, or a push applied to an object, tends to force the object away from the source of the compression. Again, no movement can occur until the applied compression exceeds the load of the object. Muscle cells can use energy to shorten and generate tension through interactions between thick and thin filaments, but not to lengthen and generate compression. In other words, muscle cells can pull, but they cannot push.

Each power stroke shortens the sarcomere by about 0.5%. The entire muscle shortens at the same rate because all the sarcomeres contract together. The speed of the shortening

SPOTLIGHT

Figure 10-10

Events at the Neuromuscular Junction

A single axon may branch to control more than one skeletal muscle fiber, but each muscle fiber has only one neuromuscular junction (NMJ). At the NMJ, the axon terminal of the neuron lies near the motor end plate of the muscle fiber.

The action potential generated at the motor end plate now sweeps across the entire membrane surface. The effects are almost immediate because an action potential is an electrical event that flashes like a spark across the sarcolemmal surface. The effects are brief because the ACh has been removed, and no further stimulus acts upon the motor end plate until another action potential arrives at the axon terminal.

3

When the action potential reaches the neuron's axon terminal, permeability changes in its membrane trigger the exocytosis of ACh into the synaptic cleft. Exocytosis occurs as vesicles fuse with the neuron's plasma membrane.

Motor end plate

4

ACh molecules diffuse across the synaptic cleft and bind to ACh receptor membrane channels. ACh binding opens the membrane channel on the surface of the motor end plate. Because the extracellular fluid contains a high concentration of sodium ions, and sodium ion concentration inside the cell is very low, sodium ions rush into the cytosol.

5

The sudden inrush of sodium ions results in the generation of an action potential in the sarcolemma. ACh is removed from the synaptic cleft in two ways. ACh either diffuses away from the synapse, or it is broken down by AChE into acetic acid and choline. This removal closes the ACh receptor membrane channels. The muscle fiber pictured above indicates the propagation of the action potential along the sarcolemma.

SPOTLIGHT

Figure 10–11

Excitation–Contraction Coupling

- 1 Neural Control**
 A skeletal muscle fiber contracts when stimulated by a motor neuron at a neuromuscular junction. The stimulus arrives in the form of an action potential at the axon terminal.
- 2 Excitation**
 The action potential causes the release of ACh into the synaptic cleft, which leads to excitation—the production of an action potential in the sarcolemma.
- 3 Release of Calcium Ions**
 This action potential travels along the sarcolemma and down T tubules to the triads. This triggers the release of calcium ions (Ca^{2+}) from the terminal cisternae of the sarcoplasmic reticulum.
- 4 Contraction Cycle Begins**
 The contraction cycle begins when the calcium ions (Ca^{2+}) bind to troponin, resulting in the exposure of the active sites on the thin filaments. This allows cross-bridge formation and will continue as long as ATP is available.
- 5 Sarcomere Shortening**
 As the thick and thin filaments interact, the sarcomeres shorten, pulling the ends of the muscle fiber closer together.
- 6 Generation of Muscle Tension**
 During the contraction, the entire skeletal muscle shortens and produces a pull, or tension, on the tendons at either end.

depends on the cycling rate (the number of power strokes per second). The greater the load, the slower the cycling rate.

To understand how the contraction cycle produces tension in a muscle fiber, imagine a tug-of-war team. Each member reaches forward, grabs the rope with both hands (one hand in front of the other), and pulls it toward itself. This grab-and-pull corresponds to cross-bridge attachment and pivoting. Then they let go of the rope, reach forward and grab it, and pull once again. Each person's actions are not synchronized with the rest of the team. At any given time, some people are reaching and grabbing, some are pulling, and others are letting go. (If everyone let go at the same time, the opponents would pull the rope away.) The amount of tension produced depends on how many people are pulling at the same time.

The situation is similar in a muscle fiber. The myosin heads along a thick filament work together to pull a thin filament toward the center of the sarcomere. Each myofibril consists of a string of sarcomeres, and in a contraction all the thin filaments are pulled toward the centers of the sarcomeres.

Clinical Note Tetanus

Beware of rusty nails! However, it's not the rust or the nail, but instead an infection by the very common bacterium *Clostridium tetani* that is dangerous. The resulting disease is called **tetanus**. *Clostridium* bacteria are found in soil and virtually everywhere else in the environment, but they can thrive only in tissues with a low oxygen level. For this reason, a deep puncture wound, such as that from a nail, is much more likely to result in tetanus than a shallow, open, freely bleeding cut. When active in body tissues, these bacteria release a powerful neurotoxin that affects the central nervous system. Motor neurons, which control skeletal muscles throughout the body, are particularly sensitive to it. The toxin suppresses the mechanism that inhibits motor neuron activity. The result is sustained, powerful contractions of skeletal muscles throughout the body. The disease is also called *lockjaw* because patients find it difficult to open the mouth.

Severe tetanus has a 40–60% mortality rate. In other words, for every 100 people who develop severe tetanus, 40 to 60 die. Approximately 500,000 cases of tetanus occur worldwide each year, but only about 100 of them occur in the United States, thanks to an effective immunization program beginning in childhood. (Recommended immunization involves a “tetanus shot” followed by a booster shot every 10 years.) In unimmunized patients, early administration of an antitoxin prevents severe symptoms. However, this treatment does not reduce signs and symptoms that have already appeared.

Figure 10–13 reviews the contraction process. Steps 1–5 of this figure show the release of ACh at the neuromuscular junction, continuing through excitation–contraction coupling to the beginning of the contraction cycle.

Relaxation

How long does a contraction last? Its duration depends on three factors: (1) the period of stimulation at the neuromuscular junction (NMJ), (2) the presence of free calcium ions in the cytosol, and (3) the availability of ATP. A single action potential has only a brief effect on a muscle fiber, so a contraction will continue only if additional action potentials arrive at the NMJ in rapid succession. When they do, the continual release of ACh produces a series of action potentials in the sarcolemma that keeps the Ca^{2+} level elevated in the cytosol. Under these conditions, the contraction cycle will be repeated over and over.

Steps 6–10 of **Figure 10–13** show what happens if just one action potential arrives at the neuromuscular junction. This starts with the breakdown of released ACh in the synaptic cleft by *acetylcholinesterase*, or *AChE*. Inside the muscle fiber, the permeability changes in the sarcoplasmic reticulum (SR) are also very brief. For these reasons, the Ca^{2+} concentration in the cytosol will quickly return to its normal resting level. Two mechanisms are involved in this process: (1) active Ca^{2+} transport into the SR and (2) active Ca^{2+} transport across the sarcolemma into the extracellular fluid.

Clinical Note Rigor Mortis

When death occurs, circulation ceases and the skeletal muscles are deprived of nutrients and oxygen. Within a few hours, the skeletal muscle fibers run out of ATP and the sarcoplasmic reticulum becomes unable to pump calcium ions out of the cytosol. Calcium ions diffusing into the cytosol from the extracellular fluid or leaking out of the SR then trigger a sustained contraction. Without ATP, the cross-bridges cannot detach from the active sites, so skeletal muscles throughout the body become locked in the contracted position. Because all the skeletal muscles are involved, the body becomes “stiff as a board.” This physical state—**rigor mortis**—lasts until the lysosomal enzymes released by autolysis (the process of self-digestion) break down the Z lines and titin filaments. Rigor mortis begins 2–7 hours after death and ends after 1–6 days or when decomposition begins. The timing depends on environmental factors, such as temperature. Forensic pathologists (scientists who study the causes of disease and death) can estimate the time of death based on the degree of rigor mortis and environmental conditions.

1

Contraction Cycle Begins

The contraction cycle involves a series of interrelated steps. It begins with the arrival of calcium ions (Ca^{2+}) within the zone of overlap in a sarcomere.

2

Active-Site Exposure

Calcium ions bind to troponin, weakening the bond between actin and the troponin–tropomyosin complex. The troponin molecule then changes position, rolling the tropomyosin molecule away from the active sites on actin and allowing interaction with the energized myosin heads.

3

Cross-Bridge Formation

Once the active sites are exposed, the energized myosin heads bind to them, forming cross-bridges.

RESTING SARCOMERE

In the resting sarcomere, each myosin head is already “energized”—charged with the energy that will be used to power a contraction. Each myosin head points away from the M line. In this position, the myosin head is “cocked” like the spring in a mousetrap. Cocking the myosin head requires energy, which is obtained by breaking down ATP; in doing so, the myosin head functions as ATPase, an enzyme that breaks down ATP. At the start of the contraction cycle, the breakdown products, ADP and phosphate (represented as P), remain bound to the myosin head.

4

Myosin Head Pivoting

After cross-bridge formation, the energy that was stored in the resting state is released as the myosin head pivots toward the M line. This action is called the power stroke; when it occurs, the bound ADP and phosphate group are released.

5

Cross-Bridge Detachment

When another ATP binds to the myosin head, the link between the myosin head and the active site on the actin molecule is broken. The active site is now exposed and able to form another cross-bridge.

6

Myosin Reactivation

Myosin reactivation occurs when the free myosin head splits ATP into ADP and P. The energy released is used to recock the myosin head.

**CONTRACTED SARCOMERE**

The entire cycle is repeated several times each second, as long as Ca^{2+} concentrations remain elevated and ATP reserves are sufficient. Calcium ion levels will remain elevated only as long as action potentials continue to pass along the T tubules and stimulate the terminal cisternae. Once that stimulus is removed, the calcium channels in the SR close and calcium ion pumps pull Ca^{2+} from the cytosol and store it within the terminal cisternae. Troponin molecules then shift position, swinging the tropomyosin strands over the active sites and preventing further cross-bridge formation.

Figure 10–13 Steps Involved in Skeletal Muscle Contraction and Relaxation.

Of the two, transport into the SR is far more important. Almost as soon as the calcium ions have been released, the SR returns to its normal permeability and begins to actively take up these ions from the surrounding cytosol. As the Ca^{2+} concentration in the cytosol falls, earlier events reverse themselves: (1) Calcium ions detach from troponin, (2) troponin returns to its original position, and (3) tropomyosin once again covers the active sites on actin. This ends the contraction.

The sarcomeres do not automatically return to their original length. The sarcomeres in a muscle fiber can shorten and develop tension, but there is no active mechanism for reversing the process—the power stroke cannot be reversed to push the Z lines farther apart. External forces must act on the contracted muscle fiber to stretch the myofibrils and sarcomeres to their original dimensions. We describe those forces in Section 10-5.

Checkpoint

10-5 Muscle fibers produce different amounts of tension depending on sarcomere length and frequency of stimulation

Learning Outcome Describe the mechanism responsible for the different amounts of tension produced in a muscle fiber.

When sarcomeres shorten in a contraction, they shorten the muscle fiber. The tension produced by an individual muscle fiber can vary, and in this section, we consider the specific factors involved in that variation.

The amount of tension produced by an individual muscle fiber in a contraction ultimately depends on the number of power strokes performed by cross-bridges. The number of contracting sarcomeres within the muscle fiber is fixed, because calcium ions are released from all triads in the muscle fiber at the same time. For this reason, a muscle fiber is either all “on” (producing tension) or all “off” (relaxed).

The tension produced by an individual muscle fiber *does* vary, however, for other reasons. Tension production is greatest when a muscle is stimulated at its optimal length. A couple of factors are important:

- Tension production depends on the fiber’s resting length at the time of stimulation, which determines the amount of overlap between thick and thin filaments.
- It also depends on the frequency of stimulation, which affects the internal concentration of calcium ions and thus the amount bound to troponin.

Length–Tension Relationships

Figure 10–14 shows the effect of sarcomere length on active tension. When many people pull on a rope, the amount of tension produced is proportional to the number of people pulling. Similarly, in a skeletal muscle fiber, the amount of tension generated during a contraction depends on the number of power strokes performed by cross-bridges in each of the myofibrils. The number of cross-bridges that can form, in turn, depends on the amount of overlap between thick filaments and thin filaments within these sarcomeres. When the muscle fiber is stimulated to contract, only myosin heads in the zones of overlap can bind to active sites and produce tension. For these reasons, we can relate the tension produced by the entire muscle fiber to the length of individual sarcomeres, a concept known as the **length–tension relationship**.

A sarcomere works most efficiently within an optimal range of lengths. When the resting sarcomere length is within this range, the maximum number of cross-bridges can form, and the maximum amount of tension is produced. If the resting sarcomere length falls outside the range—if the sarcomere is stretched and lengthened or compressed and shortened—it cannot produce as much tension when stimulated. An increase in sarcomere length reduces the tension produced by reducing the zone of overlap and, hence, the number of potential cross-bridges.

A decrease in the resting sarcomere length reduces efficiency because the stimulated sarcomere cannot shorten very much before the thin filaments extend across the center of the sarcomere (M line) and collide with or overlap the thin filaments of the opposite side. This interferes with the binding of myosin heads to active sites and the propagation of the action potential along the T tubules. Because the number of cross-bridges is reduced, tension declines in the stimulated muscle fiber. Tension production falls to zero when the resting sarcomere is at its shortest length. At this point, the thick filaments are jammed against the Z lines and no further shortening is possible. Although cross-bridge binding can still occur, the myosin heads cannot produce a power stroke and generate tension because the thin filaments cannot move.

In summary, skeletal muscle fibers contract most forcefully when stimulated within the range of their optimal

Figure 10-14 The Effect of Sarcomere Length on Active Tension.

What happens to sarcomere length if the zone of overlap is decreased?

resting lengths (**Figure 10-14**). The arrangement of skeletal muscles, connective tissues, and bones normally prevents extreme compression or excessive stretching of muscle fibers. For example, straightening the elbow stretches the *biceps brachii*, but the bones and ligaments of the elbow stop this movement before the muscle fibers stretch too far. During an activity such as walking, in which muscles contract and relax cyclically, muscle fibers are stretched to a length very close to “ideal” before they are stimulated to contract. When muscles must contract over a larger range of resting lengths, they often “team up” to improve efficiency. (We discuss the mechanical principles involved in Chapter 11.)

Frequency of Stimulation

A single stimulation produces a single contraction, or *twitch*, that may last 7–100 milliseconds, depending on the muscle stimulated. A single twitch is so brief that there isn’t enough time to activate a significant percentage of the available cross-bridges. For this reason, although muscle twitches can be produced by electrical stimulation in a laboratory, they are ineffective in performing useful work. However, if a second twitch occurs before the tension returns to zero, tension will peak at a higher level, because additional cross-bridges will form. Think of a child on a swing: They move their legs back and forth slightly to start the swing moving, but if they

exert more effort the second time, they swing higher because the energy of the second motion is added to the energy remaining from the first. Likewise, each successive contraction begins before the tension has fallen to the resting level, so the tension continues to increase until it peaks. To understand this process, we need to follow the changes that occur as the rate of stimulation increases. Although measuring twitches is useful experimentally, all consciously and subconsciously directed muscular activities—standing, walking, running, reaching, and so forth—involve sustained muscular contractions rather than twitches.

Twitches

A **twitch** is a single stimulus–contraction–relaxation sequence in a muscle fiber. Twitches vary in duration depending on the type of muscle, its location, internal and external environmental conditions, and other factors. For example, twitches in an eye muscle fiber can be as brief as 7.5 msec, but a twitch in a muscle fiber from the *soleus* (a small calf muscle) lasts about 100 msec. **Figure 10–15a** is a **myogram**, or graphic representation, showing tension development in muscle fibers from various skeletal muscles. As shown, the twitch in the *gastrocnemius* muscle, a prominent calf muscle, is intermediate in duration.

Figure 10–15b details the phases of a 40-msec twitch in a muscle fiber from the gastrocnemius. We can divide a single twitch into a *latent period*, a *contraction phase*, and a *relaxation phase*:

1. The **latent period** begins at stimulation and lasts about 2 msec. During this period, the action potential sweeps across the sarcolemma, and the SR releases calcium ions. The muscle fiber does not produce tension during the latent period, because the contraction cycle has yet to begin.
2. In the **contraction phase**, tension increases to a peak. As the tension increases, calcium ions are binding to troponin, active sites on thin filaments are being exposed, and cross-bridge interactions are occurring. For this muscle fiber, the contraction phase ends about 15 msec after stimulation.
3. The **relaxation phase** lasts about 25 msec. During this period, the Ca^{2+} level is decreasing as calcium ions are pumped back into the SR, active sites are being covered by tropomyosin, and the number of active cross-bridges is declining as they detach. As a result, tension decreases to the resting level.

Treppe

If a skeletal muscle fiber is stimulated a second time immediately after the relaxation phase of a twitch has ended, the resulting contraction will develop a slightly higher maximum tension than did the first contraction. The increase in maximum tension shown in **Figure 10–16a** will continue over the

first 30–50 stimulations. After that, the amount of tension produced will remain constant. This pattern is called **treppe** (TREP-eh), a German word for “staircase,” because the tension rises in stages, like the steps in a staircase. The rise is thought to result from a gradual increase in the concentration of Ca^{2+} in the cytosol, in part because the calcium ion pumps in the SR have too little time to recapture the ions between stimulations. Most skeletal muscles don’t undergo treppe. However, treppe is a phenomenon in cardiac muscle. It occurs if stimuli of the same intensity are sent to the muscle fiber after a latent period.

Figure 10–15 The Development of Tension in a Twitch.

a A myogram showing differences in tension over time for a twitch in the fibers from different skeletal muscles.

b The details of tension over time for a single twitch in a fiber of the gastrocnemius muscle. Notice the presence of a latent period. It corresponds to the time needed for the propagation of an action potential and the subsequent release of calcium ions by the sarcoplasmic reticulum.

Figure 10–16 Effects of Repeated Stimulations.

Wave Summation

If a second stimulus arrives before the relaxation phase has ended, a second, more powerful contraction occurs. The addition of one twitch to another in this way is the summation of twitches, or **wave summation** (Figure 10–16b). The duration of a single twitch determines the maximum time available for wave summation. For example, if a twitch lasts 20 msec (1/50 sec), subsequent stimuli must be separated by less than 20 msec—a stimulation rate of more than 50 stimuli per second. This rate is usually expressed in terms of *stimulus frequency*, which is the number of stimuli per unit time. In this instance, a stimulus frequency of greater than 50 per second produces wave summation, whereas a stimulus frequency of less than 50 per second produces individual twitches and treppe.

Incomplete and Complete Tetanus

If the stimulation continues and the muscle fiber is never allowed to relax completely, tension will increase until it

reaches its maximum potential tension, called *tetanus* (*tetanos*, convulsive tension), which is about four times the maximum produced by treppe. A muscle producing almost maximum tension during rapid cycles of contraction and relaxation is in **incomplete tetanus** (Figure 10–16c).

When a higher stimulation frequency eliminates the relaxation phase, **complete tetanus** occurs (Figure 10–16d). In this situation, action potentials arrive so rapidly that the SR does not have time to reclaim the calcium ions. The high Ca^{2+} concentration in the cytosol prolongs the contraction, making it continuous. During a tetanic contraction, there is enough time for essentially all the potential cross-bridges to form, and tension peaks.

13. Why does a muscle that has been overstretched produce minimal tension?

See the blue Answers tab at the back of the book.

10-6 Skeletal muscles produce increased tension by recruiting additional motor units

Learning Outcome Compare the different types of skeletal muscle contraction.

Now that you are familiar with the basic mechanisms of muscle contraction at the level of the individual muscle fiber, we can begin to examine the performance of skeletal muscles—the organs of the muscular system. In this section, we consider the coordinated contractions of an entire population of skeletal muscle fibers.

The amount of tension produced by a muscle as a whole is the sum of the tensions generated by its individual muscle fibers, since they are all pulling together. For this reason, regulating the number of stimulated muscle fibers will control the tension of a skeletal muscle. This regulation involves both the number of muscle fibers innervated by a single motor neuron and how many of these motor neurons are stimulated.

The ability to control the amount of tension exerted by our skeletal muscles is critical during normal movements so that our muscles contract smoothly, not jerkily. As we will see, muscle contractions differ. In *isotonic contractions*, the muscle length changes with a constant force. In *isometric contractions*, the length of the muscle does not change with a constant force. Furthermore, isotonic contractions are further

divided into either concentric (muscle shortens) or eccentric (muscle lengthens) contractions. We discuss these different types below.

As muscle fibers actively shorten, they pull on the attached connective tissue fibers and tendons, which become stretched. The tension is transferred in turn to bones, which are moved against an external load. (We discuss the interactions between the muscular and skeletal systems in Chapter 11.)

Motor Units

A typical skeletal muscle contains thousands of muscle fibers. Some motor neurons control a few muscle fibers, but most control hundreds or thousands of them through multiple axon terminals. A **motor unit** is a motor neuron and all the muscle fibers that it controls. The size of a motor unit indicates how fine, or precise, a movement can be. Small motor units, with four to six muscle fibers, are found in the muscles of the eyes and fingers, where precise control is extremely important. Large motor units, with 1000–2000 muscle fibers, are found in weight-bearing muscles of the thighs and hips, where precise control is less urgent. The muscle fibers of each motor unit are intermingled with those of other motor units (**Figure 10-17a**). Because of this intermingling, the direction of pull exerted on the tendon does not change when the number of activated motor units varies.

10

Figure 10-17 The Arrangement and Activity of Motor Units in a Skeletal Muscle.

You may have seen or felt an involuntary “muscle twitch” under the skin. Such a muscle twitch is called a **fasciculation** (fa-sik-ū-LĀ-shun). Unlike the twitches discussed earlier, a fasciculation involves more than one muscle fiber. It is the synchronous contraction of a motor unit.

Recruitment

When the arm moves, specific groups of motor neurons in the spinal cord are stimulated. The contraction begins with the activation of the smallest motor units in the stimulated muscle. These motor units generally contain muscle fibers that contract slowly. As the movement continues, larger motor units containing faster and more powerful muscle fibers are activated, and tension rises steeply. The smooth but steady increase in muscular tension produced by increasing the number of active motor units is called **recruitment**.

Peak tension occurs when all motor units in the muscle contract in a state of complete tetanus. Such powerful contractions do not last long, however, because the individual muscle fibers soon use up their available energy reserves. During a sustained contraction, motor units are activated on a rotating basis, so some of them are resting and recovering while others are actively contracting. In this “relay team” approach, called *asynchronous motor unit summation*, each motor unit can recover somewhat before it is stimulated again (**Figure 10–17b**). As a result, when muscles contract for sustained periods, they produce slightly less than maximum tension.

Muscle Tone

In any skeletal muscle, some motor units are always active, even when the entire muscle is not contracting. Their contractions do not produce enough tension to cause movement, but they do tense and firm the muscle. This resting tension in a skeletal muscle is called **muscle tone**. A muscle with little muscle tone appears limp and soft, whereas one with moderate muscle tone is firm and solid. Different motor units are stimulated at different times so some individual muscle fibers can relax while others maintain a constant tension in the attached tendon.

Resting muscle tone stabilizes the positions of bones and joints. For example, in muscles involved with balance and posture, enough motor units are stimulated to produce the tension needed to maintain body position. Muscle tone also helps prevent sudden, uncontrolled changes in the positions of bones and joints. In addition to bracing the skeleton, the elastic nature of muscles and tendons lets skeletal muscles act as shock absorbers that cushion the impact of a sudden bump or shock. Heightened muscle tone accelerates the recruitment process during a voluntary contraction because some of the motor units are already stimulated. Strong muscle tone also makes skeletal muscles appear firm and well defined, even at rest.

Activated muscle fibers use energy, so the greater the muscle tone, the higher the “resting” rate of *metabolism* (all the chemical reactions occurring in the body). Increasing this rate is one of the significant effects of exercise in a weight-loss program. Weight is lost when the daily energy use exceeds the daily energy intake from food. Although exercise consumes energy very quickly, the period of activity is usually quite brief. In contrast, elevated muscle tone increases resting energy consumption by a small amount, but the effects are cumulative, and they continue 24 hours per day.

Types of Muscle Contractions

We can classify muscle contractions as *isotonic* or *isometric* based on their pattern of tension production.

Isotonic Contractions

In an **isotonic contraction** (*iso-*, equal + *tonos*, tension), tension increases and the skeletal muscle’s length changes. Lifting an object off a desk, walking, and running involve isotonic contractions. There are two types of isotonic contractions: concentric and eccentric.

Isotonic Concentric Contractions. In an **isotonic concentric contraction**, the muscle tension *exceeds* the load, and the muscle *shortens*. Consider an experiment with a skeletal muscle that is 1 cm² in cross-sectional area and can produce about 4 kg (8.8 lb) of tension in complete tetanus. That is, 4 kg is the muscle’s maximum potential tension. If we hang a load of 2 kg (4.4 lb) from that muscle and stimulate it, the muscle will shorten (**Figure 10–18a**). Before the muscle can shorten, the cross-bridges in its muscle fibers must produce enough tension to overcome the load—in this case, the 2-kg weight. At first, tension in the muscle rises until the tension in the tendon exceeds the load. Then, as the muscle shortens, its tension remains constant at a value that just exceeds the load. The term *isotonic* originated from this type of experiment.

In the body, however, the situation is more complicated. Muscles are not always positioned directly above the load, and they are attached to bones rather than to static weights. Changes in the positions of the muscle and the articulating bones, the effects of gravity, and other mechanical and physical factors interact to increase or decrease the load the muscle must overcome as a movement proceeds. Nevertheless, during a concentric contraction, the peak tension produced exceeds that load.

The speed of shortening varies with the difference between the amount of tension produced and the size of the load. If all the motor units are stimulated and the load is light, the muscle will shorten very quickly. In contrast, if the muscle barely produces enough tension to overcome the load, it will shorten very slowly.

Figure 10–18 Concentric, Eccentric, and Isometric Contractions.**a Isotonic concentric contraction.**

A muscle is attached to a weight (2 kg) that is $\frac{1}{2}$ its maximum potential tension (4 kg). When stimulated, it develops enough tension to lift the weight. The tension remains constant, but the muscle shortens.

**b Isotonic eccentric contraction.**

The tension remains constant, but the muscle lengthens.

**c Isometric contraction.**

When stimulated, the tension rises, but the muscle length stays the same.

Isotonic Eccentric Contractions. In an **isotonic eccentric** (ek-SEN-trik) **contraction**, the peak tension developed is *less than* the load, and the muscle *elongates* due to the contraction of another muscle or the pull of gravity. **Figure 10-18b** shows what happens in our experiment if we attach a 6-kg weight to the muscle and then stimulate the muscle (6 kg is 2 kg greater than the 4-kg maximum tension potential). Although cross-bridges form and tension rises to peak values, the muscle cannot overcome the load of the weight, so it elongates. Think of a tug-of-war team trying to stop a moving car. Although everyone pulls as hard as they can, the rope slips through their fingers. The speed of elongation depends on the difference between the amount of tension developed by the active muscle fibers and the size of the load. In our analogy, the team might slow down a small car, but would have little effect on a large truck.

Isotonic eccentric contractions are very common, and they are important in a variety of movements. In these movements, one exerts precise control over the amount of tension produced. By varying the tension in an eccentric contraction, one can control the rate of elongation, just as a person can vary the tension in a concentric contraction.

During physical training, people commonly perform cycles of isotonic concentric and eccentric contractions, as when they do biceps curls by holding a weight in their hand and slowly flex and extend their elbow. The flexion involves concentric contractions that exceed the load posed by the weight. During extension, the same muscles are active, but the contractions are eccentric. The tension produced isn't sufficient to overcome the force of gravity, but it is enough to control the speed of movement.

Isometric Contractions

In an **isometric contraction** (*metric*, measure), the whole muscle does not change length, and the tension produced never exceeds the load. This time in our experiment the same 6-kg weight is applied to the muscle, but the muscle is fixed at both ends, so it cannot shorten or elongate (**Figure 10-18c**). Examples of isometric contractions include carrying a bag of groceries and holding the head up. Many of the reflexive muscle contractions that keep the body upright while standing or sitting involve isometric contractions of muscles that oppose the force of gravity.

Notice that when one performs an isometric contraction, the contracting muscle bulges, but not as much as it does during an isotonic contraction. In an isometric contraction, the muscle *as a whole* does not shorten, but the individual muscle fibers shorten as connective tissues stretch. The muscle fibers cannot shorten further because the tension does not exceed the load.

Normal daily activities involve a combination of isotonic and isometric muscular contractions. While sitting and reading, isometric contractions of postural muscles stabilize the vertebrae to maintain an upright position. When turning a page, a combination of concentric and eccentric isotonic contractions moves the arm, forearm, hand, and fingers.

Tips

During an *isotonic* contraction, such as lifting a baby, muscle tension remains constant while muscle length changes. During an *isometric* contraction, such as holding a baby at arm's length, muscle length remains constant but muscle tension changes.

Load and Speed of Contraction

A light object can be lifted more rapidly than a heavy one because load and the speed of contraction are inversely related. If the load is less than the tension produced, an isotonic concentric contraction will occur, and the muscle will shorten. The heavier the load, the longer it takes for the movement to begin, because muscle tension (which increases gradually) must exceed the load before shortening can occur (**Figure 10-19**). The contraction itself proceeds more slowly. In the muscle fiber, the speed of cross-bridge power strokes is reduced as the load increases.

For each muscle, an optimal combination of tension and speed exists for any given load. If you have ever watched a stage of the 23-day Tour de France bicycle race, you are probably already aware of this fact. When the riders are cruising along comfortably, their thigh and leg muscles are working at an optimal combination of speed and tension. When they

Figure 10-19 Load and Speed of Contraction. The heavier the load on a muscle, the longer it will take for the muscle to begin to shorten and the less the muscle will shorten.

start up a hill, the load increases. Their muscles must now develop more tension, and they move more slowly; they are no longer working at optimal efficiency. If they then shift to a lower gear, the load on their muscles decreases and their speed increases, and the muscles are once again working efficiently.

Muscle Relaxation and the Return to Resting Length

As we noted earlier, there is no active mechanism for returning shortened muscle fibers to their resting length. After a contraction, a muscle returns to its original length through a combination of elastic forces, opposing muscle contractions, and gravity.

Elastic Forces

When a contraction ends, some of the energy initially “spent” in stretching the tendons and distorting intracellular organelles is recovered as they recoil or rebound to their original dimensions. This elasticity gradually helps return the muscle fibers in the muscle to their optimal resting length.

Opposing Muscle Contractions

The contraction of *opposing muscles*, those that perform opposite actions, can return a muscle to its resting length more quickly than elastic forces can. Consider the muscles of the arm that flex or extend the elbow. Contraction of the *biceps brachii* (BRĀ-kē-tī) on the anterior part of the arm flexes the elbow, and contraction of the *triceps brachii* on the posterior part of the arm extends the elbow. When the biceps brachii contracts, the triceps brachii is stretched. When the biceps brachii relaxes, contraction of the triceps brachii extends the elbow and stretches the muscle fibers of the biceps brachii to their original length.

Gravity

Gravity may assist opposing muscle groups in quickly returning a muscle to its resting length after a contraction. For example, imagine the biceps brachii fully contracted with the elbow pointed at the ground. When the muscle relaxes, gravity will pull the forearm down and stretch the muscle. However, some active muscle tension is needed to control the rate of movement and to prevent damage to the joint. In this example, isotonic eccentric contraction of the biceps brachii can be used to control the movement.

14. Can a skeletal muscle contract without shortening? Explain.

See the blue Answers tab at the back of the book.

10-7 To maintain regular muscle fiber activity, energy and recovery are required

Learning Outcome Describe the mechanisms by which muscle fibers obtain the energy to power contractions.

Normal muscle function requires (1) substantial intracellular energy reserves, (2) a normal circulatory supply, (3) a normal blood oxygen level, and (4) a blood pH within normal limits. Anything that interferes with any of these factors will reduce the efficiency of muscle activity and cause premature muscle fatigue. For example, reduced blood flow from tight clothing, heart problems, or blood loss slows the delivery of oxygen and nutrients, accelerates the buildup of lactate and hydrogen ions, and leads to muscle fatigue.

Muscle metabolism is the sum of the chemical and physical changes that occur within muscle tissue. It involves generating the energy for contraction, using that energy, and then recovering from energy expenditure. The only energy source used directly for muscle contraction is ATP, and available stores are depleted within 4–6 seconds in active muscles. ATP is generated by direct phosphorylation of ADP by creatine phosphate, anaerobic metabolism (glycolysis), and aerobic metabolism (citric acid cycle and electron transport chain). This section discusses these processes.

ATP Generation and Muscle Fiber Contraction

A single muscle fiber may contain 15 billion thick filaments. When that muscle fiber is actively contracting, each thick filament breaks down around 2500 ATP molecules per second. Even a small skeletal muscle contains thousands of muscle fibers, so the ATP demands of a contracting skeletal muscle are enormous.

In practical terms, the demand for ATP in a contracting muscle fiber is so high that it would be impossible to have all the necessary energy available as ATP before the contraction begins. Instead, a resting muscle fiber contains only enough ATP and other high-energy compounds to sustain a contraction until additional ATP can be generated. Throughout the rest of the contraction, the muscle fiber will generate ATP at nearly the same rate as it is used. Let's learn how this works.

ATP and Creatine Phosphate Reserves

The primary function of ATP is to transfer energy from one location to another rather than to store it long term. At rest, a skeletal muscle fiber produces more ATP than it needs. Under these conditions, ATP transfers energy to creatine. **Creatine** (KRĒ-uh-tēn) is a small molecule that muscle cells assemble from fragments of amino acids. The energy transfer creates another high-energy compound, **creatine phosphate (CP)**, also known as *phosphocreatine*:

Table 10–1 Sources of Energy in a Typical Muscle Fiber

Energy Source	Utilization Process	Initial Available Quantity	Number of Twitches Supported by Each Energy Source Alone	Duration of Isometric Tetanic Contraction Supported by Each Energy Source Alone
ATP	ATP → ADP + P	3 mmol	10	2 sec
CP	ADP + CP → ATP + C	20 mmol	70	15 sec
Glycogen	Glycolysis (anaerobic metabolism)	100 mmol	670	130 sec
Glycogen	Aerobic metabolism	100 mmol	12,000	2400 sec (40 min)

During a contraction, each myosin head breaks down ATP, producing ADP and phosphate. The energy stored in creatine phosphate is then used to “recharge” ADP, converting it back to ATP through the reverse reaction:

The enzyme that catalyzes this reaction is **creatine kinase** (KĪ-nāz; **CK**). When muscle cells are damaged, CK leaks across the plasma membranes and into the bloodstream. For this reason, a high blood concentration of CK usually indicates serious muscle damage.

Table 10–1 compares the energy sources of a representative muscle fiber. A resting skeletal muscle fiber contains about six times as much creatine phosphate as readily available ATP, but when a muscle fiber is undergoing a sustained contraction, these energy reserves are exhausted in only about 15 seconds. The muscle fiber must then rely on other mechanisms to generate ATP from ADP.

ATP Generation

As we saw in Chapter 3, most cells in the body generate ATP through (1) glycolysis in the cytoplasm and (2) aerobic metabolism in mitochondria.

Glycolysis. Glycolysis is the anaerobic breakdown of glucose to pyruvate in the cytosol of a cell. It is an **anaerobic process** because it does not require oxygen. Glycolysis provides a net gain of 2 ATP molecules and generates 2 *pyruvate molecules* from each glucose molecule.

The glucose broken down under these conditions comes primarily from the reserves of glycogen in the sarcoplasm. *Glycogen* is a chain of glucose molecules. It is stored in granules close to the I bands of sarcomeres. Typical skeletal muscle fibers contain large glycogen reserves, which may account for 1.5% of the total muscle weight. When the muscle fiber begins to run short of ATP and CP, enzymes split the glycogen molecules, releasing glucose, which can be used to generate more ATP.

The ATP produced by glycolysis in the cytoplasm is only a small fraction of that produced by aerobic metabolism. Thus, when energy demands are relatively low and oxygen is readily

available, glycolysis is important only because it provides the substrates for aerobic metabolism in the mitochondria. Yet, because it can proceed without oxygen, glycolysis becomes an important source of energy when energy demands are at a maximum and the available supply of oxygen limits how quickly the mitochondria can produce ATP.

Aerobic Metabolism. Aerobic metabolism normally provides 95% of the ATP demands of a resting cell. In this process, mitochondria absorb oxygen, ADP, phosphate ions, and organic substrates (such as pyruvate) from the surrounding cytoplasm. The molecules then enter the *citric acid cycle* (also known as the *tricarboxylic acid cycle* or the *Krebs cycle*), an enzymatic pathway that breaks down organic molecules. The carbon atoms of the organic substrate are released as carbon dioxide. The hydrogen atoms are shuttled to respiratory complexes in the inner mitochondrial membrane, where their electrons are removed. After a series of intermediate steps involving the *electron transport chain*, the protons and electrons are combined with oxygen to form water. Along the way, large amounts of energy are released and used to make ATP. The entire process is very efficient: For each molecule of pyruvate “fed” into the citric acid cycle, the cell gains 15 ATP molecules.

Resting skeletal muscle fibers rely almost exclusively on the aerobic metabolism of fatty acids to generate ATP. These fatty acids are absorbed from the circulation. When the muscle starts contracting, the mitochondria begin breaking down molecules of pyruvate from glycolysis instead of fatty acids. Because a typical skeletal muscle fiber contains large amounts of glycogen, the shift from fatty acid metabolism to glucose metabolism makes it possible for the cell to continue contracting for an extended period, even without an external source of nutrients.

Muscle Metabolism and Varying Activity Levels

As physical exertion and muscular activity increase, the pattern of muscle fiber energy production and use changes. **Figure 10–20** illustrates **muscle metabolism** in a muscle fiber at rest and at moderate and peak levels of activity. Notice that this figure shows the results of the fact that when muscles become active, their energy consumption increases greatly.

Figure 10–20 Muscle Metabolism.**Muscle Metabolism in a Resting Muscle Fiber**

- The demand for ATP is low, and sufficient oxygen is available for mitochondria to meet that demand.
- Fatty acids are absorbed and broken down in the mitochondria, creating a surplus of ATP.
- Some mitochondrial ATP is used to convert absorbed glucose to glycogen.
- Mitochondrial ATP is also used to convert creatine to creatine phosphate (CP).
- This results in the buildup of energy reserves (glycogen and CP) in the muscle.

**Muscle Metabolism during Moderate Activity**

- The demand for ATP increases.
- There is still enough oxygen for the mitochondria to meet the increased demand, but no excess ATP is produced.
- ATP is generated primarily by aerobic metabolism of glucose from stored glycogen.
- If the glycogen reserves are low, the muscle fiber can also break down other substrates, such as fatty acids.
- All of the ATP being generated is used to power muscle contraction.

**Muscle Metabolism during Peak Activity**

- The demand for ATP is enormous. Oxygen cannot diffuse into the fiber fast enough for the mitochondria to meet that demand. Only a third of the cell's ATP needs can be met by the mitochondria (not shown).
- The rest of the ATP comes from glycolysis, and when this produces pyruvate faster than the mitochondria can utilize it, the pyruvate builds up in the cytosol.
- The pyruvate is converted to lactate. Hydrogen ions from ATP hydrolysis are not absorbed by the mitochondria.
- The buildup of hydrogen ions increases cytosol acidity, which inhibits muscle contraction, leading to rapid fatigue.

Although the muscle fiber can generate additional ATP by the anaerobic process of glycolysis during times of peak energy demands, this process has two important drawbacks. First, any underutilized pyruvate molecules produced through glycolysis are converted to *lactate*. At the same time, the hydrolytic breakdown of ATP during muscle contraction releases hydrogen ions. During aerobic metabolism, these hydrogen ions are transported into the mitochondria. However, when ATP production is relying on glycolysis, the hydrogen ions remain in the cytosol. At peak activity, both hydrogen ions and lactate build up (**Figure 10–20**). This results in an increased lactate blood level and metabolic acidosis, often referred to as *lactic acidosis*. The hydrogen ions can then lower the intracellular pH. Buffers in the sarcoplasm resist pH shifts, but these mechanisms are limited. Eventually, changes in pH affect the workings of key enzymes so that the muscle fiber can no longer contract.

Second, glycolysis is a relatively inefficient way to generate ATP. Under anaerobic conditions, each glucose molecule generates 2 pyruvate molecules, which are converted to 2 lactate molecules. In this process, the fiber gains 2 ATP molecules. However, had those 2 pyruvate molecules been catabolized aerobically in a mitochondrion, the cell would have produced 30 additional ATP.

The Recovery Period

When a muscle fiber contracts, conditions in the sarcoplasm change. Energy reserves are consumed, heat is released, and, if the contraction was at a maximum level, oxygen is less available and lactate is generated. In the **recovery period**, the conditions in muscle fibers are returned to a normal, pre-exertion level. After a period of moderate activity, muscle fibers may need several hours to recover. After sustained activity at a higher level, complete recovery can take a week.

Lactate Removal and Recycling

Glycolysis enables a skeletal muscle fiber to continue contracting even when mitochondrial activity is limited by the availability of oxygen. As we have seen, however, the anaerobic process of glycolysis and its production of lactate is not an ideal way to generate ATP. During the recovery period, when oxygen is available in abundance, lactate can be converted back to pyruvate. The pyruvate can then be used either by mitochondria to generate ATP or as a substrate for enzyme pathways that synthesize glucose and rebuild glycogen reserves. During exertion, lactate diffuses out of muscle fibers and into the bloodstream. The process continues after the exertion has ended, because the intracellular lactate concentration is still relatively high. The liver absorbs the lactate and converts it to pyruvate. About 20–30% of these new pyruvate molecules enter liver mitochondria where they are

catabolized, providing the ATP needed to convert the other 70–80% of the pyruvate molecules to glucose. (We cover these processes more fully in Chapter 25.) The glucose molecules are then released into the circulation, where they are absorbed by skeletal muscle fibers and used to rebuild their glycogen reserves. This shuffling of lactate produced in the muscles to the liver and glucose back to muscle cells is called the *Cori cycle*.

The Oxygen Debt

During the recovery period, the oxygen demand of the body's cells remains elevated above the normal resting level. The more ATP required for recovery, the more oxygen will be needed. The amount of oxygen required to restore normal, pre-exertion conditions is called the **oxygen debt**, or **excess postexercise oxygen consumption (EPOC)**.

Most of the additional oxygen consumption occurs in skeletal muscle fibers, which must restore ATP, CP, and glycogen concentrations to their former levels, and in liver cells, which generate the ATP needed to convert excess lactate to glucose. However, several other tissues also increase their rate of oxygen consumption and ATP generation during the recovery period. For example, sweat glands increase their secretory activity until normal body temperature is restored. While the oxygen debt is being repaid, breathing rate and depth are increased. As a result, even fit athletes continue to breathe heavily after they stop exercising.

Heat Production and Loss

Muscular activity generates considerable heat. During a catabolic process, such as the breakdown of glycogen or the reactions of glycolysis, a muscle fiber captures only a portion of the released energy—the rest escapes as heat. A resting muscle fiber relying on aerobic metabolism captures about 42% of the energy released in catabolism. The other 58% warms the sarcoplasm, interstitial fluid, and circulating blood. Active skeletal muscles release approximately 85% of the heat needed to maintain normal body temperature.

When anaerobic metabolism is the primary method of ATP generation, muscle fibers become less efficient at capturing energy. At peak levels of exertion, only about 30% of the released energy is captured as ATP, and the remaining 70% warms the muscle and surrounding tissues. Body temperature soon climbs, and heat loss at the skin accelerates through mechanisms introduced in Chapters 1 and 5. Heat loss continues during the recovery period.

Hormones and Muscle Metabolism

Hormones of the endocrine system adjust metabolic activities in skeletal muscle fibers. *Growth hormone* and *testosterone*

stimulate the synthesis of contractile proteins, such as actin and myosin, and the enlargement of skeletal muscles. *Thyroid hormones* elevate the rate of energy consumption in resting and active skeletal muscles. During a crisis, hormones of the adrenal gland, notably *epinephrine* (adrenaline), stimulate muscle metabolism and increase both the duration of stimulation and the force of contraction. We further examine the effects of hormones on muscle and other tissues in Chapter 18.

See the blue Answers tab at the back of the book.

10-8 Muscle performance depends on muscle fiber type and physical conditioning

Learning Outcome Relate the types of muscle fibers to muscle performance, discuss muscle hypertrophy, atrophy, and aging, and describe how physical conditioning affects muscle tissue.

We can consider muscle performance in terms of **force**, the maximum amount of tension produced by a particular muscle or muscle group, and **endurance**, the amount of time during which a person can perform a particular activity. Here we consider the factors that determine the performance capabilities of any skeletal muscle: the type, distribution, and size of muscle fibers in the muscle, and physical conditioning or training.

Types of Skeletal Muscle Fibers

The human body has three major types of skeletal muscle fibers: *fast fibers*, *slow fibers*, and *intermediate fibers*.

Fast Fibers

Most of the skeletal muscle fibers in the body are called **fast fibers** because they can reach peak twitch tension in 0.01 sec or less after stimulation. Fast fibers are large in diameter and contain densely packed myofibrils, large glycogen reserves, and relatively few mitochondria. Muscles dominated by fast fibers produce powerful contractions because the tension produced by a muscle fiber is directly proportional to the number of myofibrils. However, fast fibers fatigue rapidly because their contractions use ATP in massive amounts, and they have relatively few mitochondria to generate ATP. As a result, prolonged activity is supported primarily by anaerobic metabolism.

Slow Fibers

Slow fibers have only about half the diameter of fast fibers and take three times as long to reach peak tension after stimulation. These fibers are specialized in ways that enable them to continue contracting long after a fast fiber would have become fatigued. The most important specializations support aerobic metabolism in the numerous mitochondria.

One of the main characteristics of slow muscle fibers is that they are surrounded by a more extensive network of capillaries than fast muscle tissue. For this reason, they have a dramatically higher oxygen supply to support mitochondrial activity. Slow fibers also contain the red pigment **myoglobin** (MĪ-ō-glō-bin). This globular protein is similar to hemoglobin, the red oxygen-carrying pigment in blood. Both myoglobin and hemoglobin reversibly bind oxygen molecules. Other muscle fiber types contain small amounts of myoglobin, but it is most abundant in slow fibers. As a result, resting slow fibers hold substantial oxygen reserves that can be used during a contraction. Skeletal muscles dominated by slow fibers are dark red because slow fibers have both an extensive capillary supply and a high concentration of myoglobin.

With oxygen reserves and a more efficient blood supply, the mitochondria of slow fibers can contribute more ATP during contractions. In addition, demand for ATP is reduced because the cross-bridges in slow fibers cycle more slowly than those of fast fibers. Thus, slow fibers are less dependent on anaerobic metabolism than are fast fibers. Glycogen reserves of slow fibers are also smaller than those of fast fibers, because some of the mitochondrial energy production involves the breakdown of stored lipids rather than glycogen. **Figure 10-21** compares the appearance of fast and slow fibers.

Intermediate Fibers

Most properties of **intermediate fibers** are between those of fast fibers and slow fibers. In appearance, intermediate fibers most closely resemble fast fibers because they contain little myoglobin and are relatively pale. They have an intermediate capillary network and mitochondrial supply around them and are more resistant to fatigue than are fast fibers.

The characteristics of these three types of muscle fibers are summarized in **Table 10-2**.

Muscle Performance and the Distribution of Muscle Fibers

The percentages of fast, intermediate, and slow fibers in a skeletal muscle can be quite variable. In muscles that contain a mixture of fast and intermediate fibers, the proportion can change with physical conditioning. For example, if a muscle is used repeatedly for endurance events, some of the fast fibers will develop the appearance and functional capabilities of

Figure 10–21 Slow versus Fast Skeletal Muscle Fiber Structure.

Which skeletal muscle fiber type—slow or fast—contains more mitochondria?

Table 10–2 Properties of Skeletal Muscle Fiber Types

Property	Fast Fibers	Slow Fibers	Intermediate Fibers
Cross-sectional diameter	Large	Small	Intermediate
Time to peak tension	Rapid	Prolonged	Medium
Contraction speed	Fast	Slow	Fast
Fatigue resistance	Low	High	Intermediate
Color	White	Red	Pink
Myoglobin content	Low	High	Low
Capillary supply	Scarce	Dense	Intermediate
Mitochondria	Few	Many	Intermediate
Glycolytic enzyme concentration in sarcoplasm	High	Low	High
Sources of substrates for ATP generation during contraction (metabolism)	Carbohydrates (anaerobic)	Lipids (fatty acids), carbohydrates, proteins (amino acids) (aerobic)	Primarily carbohydrates (anaerobic)
Alternative names	Type II-B, FF (fast fatigue), white, fast-twitch glycolytic	Type I, S (slow), red, SO (slow oxidative), slow-twitch oxidative	Type II-A, FR (fast resistant), fast-twitch oxidative

intermediate fibers. The whole muscle will become more resistant to fatigue.

Muscles dominated by fast fibers appear pale and are often called **white muscles**. Chicken breasts contain “white meat” because chickens use their wings only for brief intervals, as when fleeing a predator, and the power for flight comes from the anaerobic process of glycolysis in the fast fibers of their breast muscles. As noted earlier, extensive

blood vessels and myoglobin give slow fibers a reddish color, so muscles dominated by slow fibers are known as **red muscles**. Chickens walk around all day, and these movements are powered by aerobic metabolism in the slow fibers of the “dark meat” of their legs.

What about human muscles? Most of our muscles contain a mixture of fiber types and so appear pink. However, there are no slow fibers in muscles of the eye or hand, where swift,

but brief, contractions are required. Many of our back and calf muscles are dominated by slow fibers, and these muscles contract almost continuously to maintain an upright posture. Our genes determine the percentage of fast versus slow fibers in each muscle.

Muscle Hypertrophy, Atrophy, and Effects of Aging

As a result of repeated, exhaustive stimulation, muscle fibers develop more mitochondria, a higher concentration of glycolytic enzymes, and larger glycogen reserves. Such muscle fibers have more myofibrils than do less-stimulated fibers, and each myofibril contains more thick and thin filaments. The net effect is **hypertrophy** (hĭ-PER-trō-fĕ), an enlargement of the stimulated muscle. The number of muscle fibers does not change significantly, but the whole muscle enlarges because each muscle fiber increases in diameter.

Hypertrophy occurs in muscles that have been repeatedly stimulated to produce near-maximal tension. The intracellular changes that occur increase the amount of tension produced when these muscles contract. The muscles of a bodybuilder are excellent examples of muscular hypertrophy.

In contrast, a skeletal muscle that is not regularly stimulated by a motor neuron loses muscle tone and mass. The muscle becomes soft, and the muscle fibers become smaller and weaker. This reduction in muscle size, tone, and power is called **atrophy**. Individuals paralyzed by spinal cord injuries or other damage to the nervous system gradually lose muscle tone and size in the areas affected. In *polio*, a virus attacks motor neurons in the spinal cord and brain, causing muscular paralysis and atrophy. Even a temporary reduction in muscle use can lead to muscular atrophy, as can be observed by comparing “before and after” limb muscles in someone who has worn a cast. Muscle atrophy is reversible at first but dying muscle fibers are not replaced. In extreme atrophy, the functional losses are permanent. That is why physical therapy is crucial for people who have temporarily lost mobility. Direct electrical stimulation by an external device can substitute for nerve stimulation and prevent or reduce muscle atrophy.

As we age, muscle tissue also changes. We can summarize the effects of aging on the muscular system as follows:

- *Skeletal Muscle Fibers Become Smaller in Diameter.* This reduction in size reflects a decrease in the number of myofibrils. In addition, the muscle fibers contain smaller ATP, CP, and glycogen reserves and less myoglobin. The overall effect is a reduction in skeletal muscle size, strength, and endurance, combined with a tendency to fatigue more quickly. Because cardiovascular performance also decreases with age, blood flow to active muscles does not increase with exercise as rapidly as it does in younger people. These factors interact to

produce decreases of 30–50% in anaerobic and aerobic performance by age 65.

- *Skeletal Muscles Become Less Elastic.* Aging skeletal muscles develop increasing amounts of fibrous connective tissue, a process called **fibrosis**. Fibrosis makes the muscle less flexible, and the collagen fibers can restrict movement and circulation.
- *Tolerance for Exercise Decreases.* A lower tolerance for exercise comes in part from tiring quickly and in part from reduced thermoregulation, as described in Chapter 5. Individuals over age 65 cannot eliminate the heat their muscles generate during contraction as effectively as younger people can. For this reason, they are subject to overheating.
- *The Ability to Recover from Muscular Injuries Decreases.* The number of satellite cells steadily decreases with age, and the amount of fibrous tissue increases. As a result, when an injury occurs, repair capabilities are limited. Scar tissue formation is the usual result.

Regular exercise helps control body weight, strengthens bones, and generally improves the quality of life at all ages. Extremely demanding exercise is not as important as regular exercise. In fact, extreme exercise in older individuals can damage tendons, bones, and joints.

Muscle Fatigue

We say an active skeletal muscle is **fatigued** when it can no longer perform at the required level of activity. Many factors are involved in muscle fatigue. For example, muscle fatigue has been correlated with (1) depletion of metabolic reserves within the muscle fibers, (2) damage to the sarcolemma and sarcoplasmic reticulum, (3) a decline in pH within the muscle fibers and the muscle as a whole, which decreases calcium ion binding to troponin and alters enzyme activities, and (4) a sense of weariness and a reduction in the desire to continue the activity, due to the effects of low blood pH and sensations of pain. Muscle fatigue is cumulative—the effects become more pronounced as more neurons and muscle fibers are affected. The result is a gradual reduction in the capabilities and performance of the entire skeletal muscle.

If a muscle fiber is contracting at a moderate level and ATP demands can be met through aerobic metabolism, fatigue will not occur until glycogen, fatty acids, and protein reserves are depleted. This type of fatigue affects the muscles of endurance athletes, such as marathon runners, after hours of exertion. In contrast, sprinters get a different type of muscle fatigue. When a muscle produces a sudden, intense burst of activity at peak levels, glycolysis provides most of the ATP. After just seconds to minutes, tissue pH decreases due to lactic acidosis and the buildup of hydrogen ions, and the muscle can no longer function normally.

Physical Conditioning

Physical conditioning or training enables athletes and ordinary people of all ages to improve both power and endurance. In practice, the training schedule varies, depending on whether the activity is supported primarily by anaerobic or aerobic energy production.

Energy Use in Training

Anaerobic endurance is the length of time muscular contraction can continue to be supported by the existing energy reserves of ATP and CP and by glycolysis. Conditioning for anaerobic endurance improves an individual's power. Anaerobic endurance is limited by (1) the amount of ATP and CP available, (2) the amount of glycogen available for breakdown, and (3) the ability of the muscle to tolerate lactate and the buildup of hydrogen ions generated during the period of anaerobic metabolism. Typically, the onset of muscle fatigue occurs within 2 minutes of the start of maximal activity.

Activities that require above-average levels of anaerobic endurance include a 50-meter race or swim, pole vaulting, and competitive weightlifting. These activities involve the contractions of fast fibers. The energy for the first 10–20 seconds of activity comes from the ATP and CP reserves of the cytoplasm. As these energy sources decrease, an increase in glycogen breakdown and glycolysis provides additional energy. Athletes training to improve anaerobic endurance perform frequent, brief, intensive workouts that stimulate muscle hypertrophy.

Aerobic endurance is the length of time a muscle can continue to contract while supported by mitochondrial activities. Aerobic activities do not promote muscle hypertrophy. Conditioning for aerobic endurance improves an individual's ability to continue an activity for longer periods of time. Aerobic endurance is determined primarily by the availability of substrates for aerobic respiration, which muscle fibers can obtain by breaking down carbohydrates, lipids, or proteins. Initially, many of the nutrients broken down by muscle fibers come from reserves in the sarcoplasm. Prolonged aerobic activity, however, must be supported by nutrients provided by the circulating blood. Training to improve aerobic endurance generally involves sustained low levels of muscular activity. Examples include jogging, distance swimming, and other exercises that do not require peak tension production.

Physical training, using a combination of anaerobic and aerobic exercises, should be a lifelong pursuit. The recommended schedule is to alternate an anaerobic activity such as weightlifting or resistance training, with an aerobic activity, such as swimming or brisk walking. This combination, known as *cross-training*, enhances health by both increasing muscle mass and improving aerobic endurance.

Effects of Training

During exercise, blood vessels in the skeletal muscles dilate, which increases blood flow and the supply of oxygen and nutrients to the active muscle tissue. Warm-up periods are important because they both stimulate circulation in the muscles before the serious workout begins and activate the enzyme (glycogen phosphorylase) that breaks down glycogen to release glucose. Warm-ups also increase muscle temperature and thus accelerate the contraction process. Because glucose is a preferred energy source, endurance athletes such as marathon runners typically “load” or “bulk up” on carbohydrates for the 3 days before an event. They may also consume glucose-rich

Clinical Note Delayed-Onset Muscle Soreness

Individuals sometimes experience muscle soreness the next day or several days after physical exertion. Considerable controversy exists over the source and significance of such pain, which is known as *delayed-onset muscle soreness (DOMS)*. Here are a few of its characteristics:

- DOMS is distinct from the soreness a person experiences immediately after they stop exercising. The initial short-term soreness is probably related to the biochemical events associated with muscle fatigue.
- DOMS generally begins several hours after exercise and may last 3 or 4 days.
- The degree of DOMS is highest when the activity involves isotonic eccentric contractions (in which a muscle elongates despite producing tension). Activities dominated by concentric or isometric contractions produce less soreness.
- Levels of creatine kinase and myoglobin are elevated in the blood, indicating damage to muscle plasma membranes. The nature of the activity (eccentric, concentric, or isometric) has no effect on these levels, and the levels cannot be used to predict the degree of soreness.

Three mechanisms have been proposed to explain DOMS:

- Small tears may occur in the muscle tissue, leaving muscle fibers with damaged membranes. The sarcolemma of each damaged muscle fiber permits the loss of enzymes, myoglobin, and other chemicals that may stimulate nearby pain receptors.
- The pain may result from muscle spasms in the affected skeletal muscles. In some studies, stretching the muscle after exercise reduces the degree of soreness.
- The pain may result from tears in the connective tissue and tendons of the skeletal muscle.

“sports drinks” during a competition. (We consider the risks and benefits of these practices in Chapter 25.)

Improvements in aerobic endurance result from two factors:

- *Alterations in the Characteristics of Muscle Fibers.* The proportion of fast and slow fibers in each muscle is genetically determined, and individual differences are significant. These variations affect aerobic endurance, because a person with more slow fibers in a particular muscle will be better able to perform under aerobic conditions than will a person with fewer. However, skeletal muscle cells respond to changes in the pattern of neural stimulation. Fast fibers trained for aerobic competition develop the characteristics of intermediate fibers, and this change improves aerobic endurance.
- *Improvements in Cardiovascular Performance.* Cardiovascular activity affects muscular performance by delivering oxygen and nutrients to active muscles. Physical training alters cardiovascular function by accelerating blood flow, thus improving oxygen and nutrient availability. Another important benefit of endurance training is an increase in capillaries that serve exercising muscles, providing better blood flow at the cellular level. (We examine factors involved in improving cardiovascular performance in Chapter 21.)

Checkpoint

17. Identify the three types of skeletal muscle fibers.
18. Describe muscle fatigue.
19. Describe general age-related effects on skeletal muscle tissue.
20. Why would a sprinter experience muscle fatigue before a marathon runner would?
21. Which activity would be more likely to create an oxygen debt: swimming laps or lifting weights?
22. Which type of muscle fibers would predominate in the leg muscles of someone who excels at endurance activities, such as cycling or long-distance running?

See the blue Answers tab at the back of the book.

10-9 Cardiac muscle tissue, found in the heart, produces coordinated and automatic contractions

Learning Outcome Identify the structural and functional differences between skeletal muscle fibers and cardiac muscle cells.

We introduced cardiac muscle tissue in Chapter 4, and briefly compared its properties with those of other types of muscle.

Cardiac muscle cells are found only in the heart. We begin

a more detailed examination of cardiac muscle tissue by considering its structural characteristics, and then go on to a brief discussion of its function.

Structural Characteristics of Cardiac Muscle Tissue

Like neurons and skeletal muscle fibers, cardiac muscle cells have excitable membranes. Cardiac muscle cells also contain organized myofibrils, and the presence of many aligned sarcomeres gives the cells a striated appearance.

However, there are important structural differences between skeletal muscle fibers and cardiac muscle cells, including the following:

- Cardiac muscle cells are relatively small, averaging 10–20 μm in diameter and 50–100 μm in length.
- A typical cardiac muscle cell has a single, centrally placed nucleus (**Figure 10-22a,b**), although a few may have two or more nuclei. Unlike skeletal muscle, cardiac muscle cells are typically branched.
- The T tubules in a cardiac muscle cell are short and broad, and there are no triads (**Figure 10-22c**). The T tubules encircle the sarcomeres at the Z lines rather than at the zones of overlap.
- The SR of a cardiac muscle cell lacks terminal cisternae and stores fewer calcium ions. Its tubules contact the plasma membrane as well as the T tubules (**Figure 10-22c**).
- Cardiac muscle cells are almost totally dependent on aerobic metabolism for the energy they need to continue contracting. They have energy reserves in the form of glycogen and lipid inclusions. The sarcoplasm of a cardiac muscle cell contains large numbers of mitochondria as well as abundant reserves of myoglobin, which store the oxygen needed to break down energy reserves during times of peak activity.
- Each cardiac muscle cell contacts several others at specialized sites known as *intercalated* (in-TER-ka-lā-ted) discs.

At an **intercalated disc**, the sarcolemmas of two adjacent cardiac muscle cells are extensively intertwined and bound together by gap junctions and desmosomes (**Figure 10-22a,b**). These connections help stabilize the positions of adjacent cells and maintain the three-dimensional structure of the tissue. They also allow ions to move from one cell to another so that cardiac muscle cells beat in rhythm. Therefore, two cardiac muscle cells can “pull together” with maximum efficiency because their myofibrils are essentially locked together at the intercalated disc. There the myofibrils of two interlocking muscle cells are firmly anchored to their plasma membranes.

Figure 10–22 Cardiac Muscle Tissue.**a** A light micrograph of cardiac muscle tissue.**b** A diagram of cardiac muscle tissue. Note the striations and intercalated discs.**c** Cardiac muscle tissue has short, broad T tubules and an SR that lacks terminal cisternae.

Functional Characteristics of Cardiac Muscle Tissue

The gap junctions allow ions and small molecules to move from one cell to another. These junctions create a direct electrical connection between two cardiac muscle cells. An action potential can travel across an intercalated disc, moving quickly from one cardiac muscle cell to another.

Because cardiac muscle cells are physically, chemically, and electrically connected to one another, the entire tissue resembles a single, enormous muscle cell. For this reason, cardiac muscle has been called a *functional syncytium* (sin-SISH-ē-um; a fused mass of cells).

In Chapter 20, we examine cardiac muscle physiology in detail, but here we briefly summarize the four major functional specialties of cardiac muscle:

- Cardiac muscle tissue contracts without neural stimulation. This property is called **automaticity**. Specialized cardiac muscle cells called **pacemaker cells** normally determine the timing of contractions.
- The nervous system can alter the pace or rate set by the pacemaker cells and adjust the amount of tension produced during a contraction.
- Cardiac muscle cell contractions last about 10 times as long as do those of skeletal muscle fibers. They also have longer refractory periods and do not readily fatigue.
- The properties of cardiac muscle sarcolemmas (plasma membranes) differ from those of skeletal muscle fibers. As in skeletal muscle fibers, an action potential triggers the release of calcium ions from the SR and the contraction of sarcomeres. However, an action potential in a cardiac muscle cell also makes the sarcolemma more permeable to extracellular calcium ions. Because their contractions require both intracellular and extracellular calcium ions, cardiac muscle cells are more sensitive to changes in the extracellular calcium ion concentration than are skeletal muscle fibers. As a result, individual twitches cannot undergo wave summation, and cardiac muscle tissue cannot produce tetanic contractions. This difference is important because a heart in a sustained tetanic contraction could not pump blood.

Checkpoint

23. Compare and contrast skeletal muscle tissue and cardiac muscle tissue.
24. What feature of cardiac muscle tissue allows the heart to act as a functional syncytium?

See the blue Answers tab at the back of the book.

10-10 Smooth muscle tissue contracts to move substances within internal passageways

Learning Outcome Identify the structural and functional differences between skeletal muscle fibers and smooth muscle cells and discuss the roles of smooth muscle tissue in systems throughout the body.

Smooth muscle tissue forms sheets, bundles, or sheaths around other tissues in almost every organ. In general, smooth muscle functions to coordinate the movement of substances through internal passageways. Smooth muscles have numerous roles in various body systems:

- **Integumentary System:** Smooth muscles around blood vessels regulate the flow of blood to the superficial dermis; smooth muscles of the arrector pili elevate hairs.
- **Cardiovascular System:** Smooth muscles around blood vessels control blood flow through vital organs and help regulate blood pressure.
- **Respiratory System:** Smooth muscles contract or relax to alter the diameters of the respiratory passageways and change their resistance to airflow.
- **Digestive System:** Extensive layers of smooth muscle in the walls of the digestive tract play an essential role in moving materials along the tract. Smooth muscle in the walls of the gallbladder contracts to eject bile into the digestive tract. In both the digestive and urinary systems, rings of smooth muscle called *sphincters* regulate the movement of materials along internal passageways.
- **Urinary System:** Smooth muscle tissue in the walls of small blood vessels alters the rate of filtration in the kidneys. Layers of smooth muscle in the walls of the ureters transport urine to the urinary bladder, and the contraction of the smooth muscle in the wall of the urinary bladder forces urine out of the body.
- **Reproductive System:** In males, layers of smooth muscle help move sperm along the reproductive tract and cause the ejection of glandular secretions from the accessory glands into the reproductive tract. In females, layers of smooth muscle help move oocytes (and perhaps sperm) along the reproductive tract, and contractions of the smooth muscle in the walls of the uterus expel the fetus at delivery.

Structural Characteristics of Smooth Muscle Tissue

Figure 10-23a shows typical smooth muscle tissue as seen under a light microscope.

Smooth muscle tissue, like skeletal and cardiac muscle tissues, contains actin and myosin. In skeletal and cardiac muscle cells, these proteins are organized in sarcomeres, with thin

and thick filaments. However, the internal organization of a smooth muscle cell is very different:

- Smooth muscle cells are relatively long and slender, ranging from 5 to 10 μm in diameter and from 30 to 200 μm in length.
- Each cell is spindle shaped (tapered at both ends) and has a single, centrally located nucleus.
- A smooth muscle fiber has no T tubules, and the sarcoplasmic reticulum forms a loose network throughout the sarcoplasm.
- Smooth muscle cells lack myofibrils and sarcomeres. As a result, this tissue also has no striations and is called **nonstriated muscle**.
- Thick filaments are scattered throughout the sarcoplasm of a smooth muscle cell. The myosin proteins are organized differently than in skeletal or cardiac muscle cells, and smooth muscle cells have more myosin heads per thick filament.
- The thin filaments in a smooth muscle cell are attached to **dense bodies**, structures distributed throughout the sarcoplasm in a network of intermediate filaments composed of the protein *desmin* (**Figure 10-23b**). Some of the dense bodies are firmly attached to the sarcolemma. The dense bodies and intermediate filaments anchor the thin filaments such that when sliding occurs between thin and thick filaments, the cell shortens. Dense bodies are not arranged in straight lines, so when a contraction occurs, the muscle cell twists like a corkscrew.
- Adjacent smooth muscle cells are bound together at dense bodies, transmitting the contractile forces from cell to cell throughout the tissue.
- Although smooth muscle cells are surrounded by connective tissue, the collagen fibers never unite to form tendons or aponeuroses, as they do in skeletal muscles.

Functional Characteristics of Smooth Muscle Tissue

Smooth muscle tissue differs from other muscle tissue in (1) excitation–contraction coupling, (2) length–tension relationships, (3) control of contractions, and (4) smooth muscle tone.

Excitation–Contraction Coupling

In skeletal and cardiac muscles, the trigger for contraction is the binding of calcium ions to troponin. In contrast, the trigger for smooth muscle contraction is the appearance of free calcium ions in the cytoplasm. On stimulation, a surge of calcium ions enters the cell from the extracellular fluid, and the sarcoplasmic reticulum releases additional calcium ions. The net result is a rise in the Ca^{2+} concentration throughout the cell.

Figure 10–23 Smooth Muscle Tissue.

- a** Many visceral organs contain several layers of smooth muscle tissue oriented in different directions. Here, a single sectional view shows smooth muscle cells in both longitudinal (L) and transverse (T) sections.

- b** A single relaxed smooth muscle cell is spindle shaped and has no striations. Note the changes in cell shape as contraction occurs.

Once in the sarcoplasm, the calcium ions interact with **calmodulin**, a calcium-binding protein. Calmodulin then activates the enzyme **myosin light chain kinase**, which in turn enables myosin heads to attach to actin.

Length-Tension Relationships

Because the thick and thin filaments are scattered and are not organized into sarcomeres in smooth muscle, tension development and resting length are not directly related. A stretched smooth muscle soon adapts to its new length and retains the ability to contract on demand. This ability to function over a wide range of lengths is called **plasticity**. Smooth muscle can contract over a range of lengths four times greater than that of skeletal muscle. Plasticity is especially important in digestive organs, such as the stomach, that change greatly in volume.

Despite the lack of sarcomeres, smooth muscle contractions can be just as powerful as those of skeletal muscles. Like skeletal muscle fibers, smooth muscle cells can undergo sustained contractions (as occurs when the uterus contracts during labor and delivery).

Control of Contractions

Many smooth muscle cells are not innervated by motor neurons, and the neurons that do innervate smooth muscles are not under voluntary control. We categorize smooth muscle cells as either multiunit or visceral. **Multiunit smooth muscle cells** are innervated in motor units comparable to those of skeletal muscles, but each smooth muscle cell may be connected to more than one motor neuron. In contrast, many **visceral smooth muscle cells** lack a direct contact with any motor neuron.

Clinical Note Electromyography

Electromyography (EMG) is a low-risk test used to diagnose diseases of skeletal muscle, or of the motor neurons that serve it. The neurologist places a surface electrode over the weak or cramped muscle to find out if there is abnormal activity in the muscle when it should be resting. A small needle may also be inserted directly into the affected muscle to find out how the muscle reacts when a small electrical current is applied.

Table 10–3 A Comparison of Skeletal, Cardiac, and Smooth Muscle Tissues

Property	Skeletal Muscle	Cardiac Muscle	Smooth Muscle
Fiber dimensions (diameter × length)	100 μm × up to 30 cm	10–20 μm × 50–100 μm	5–10 μm × 30–200 μm
Nuclei	Multiple, near sarcolemma	Generally single, centrally located	Single, centrally located
Filament organization	In sarcomeres along myofibrils	In sarcomeres along myofibrils	Scattered throughout sarcoplasm
Sarcoplasmic reticulum (SR)	Terminal cisternae in triads at zones of overlap	SR tubules contact T tubules at Z lines	Dispersed throughout sarcoplasm, no T tubules
Control mechanism	Neural, at single neuromuscular junction on each muscle fiber	Automaticity (pacemaker cells), neural control limited to moderating pace and tension	Automaticity (pacesetter cells), neural or hormonal control (neural control limited to moderating pace and tension)
Ca²⁺ source	Release from SR	Extracellular fluid and release from SR	Extracellular fluid and release from SR
Ca²⁺ regulation	Troponin on thin filaments	Troponin on thin filaments	Calmodulin on myosin heads
Contraction	Rapid onset; may be tetanized; rapid fatigue	Slower onset; cannot be tetanized; resistant to fatigue	Slow onset; may be tetanized; resistant to fatigue
Energy source	Aerobic metabolism at moderate levels of activity; anaerobic during maximum activity (glycolysis)	Aerobic metabolism, usually lipid or carbohydrate substrates	Primarily aerobic metabolism

Multiunit smooth muscle cells have excitable plasma membranes. They resemble skeletal muscle fibers and cardiac muscle cells in that neural activity produces an action potential that travels over the sarcolemma. However, these smooth muscle cells contract more slowly than do skeletal or cardiac muscle cells. We find multiunit smooth muscle cells in the iris of the eye, where they regulate the diameter of the pupil; within the walls of large arteries; in the arrector pili muscles of the skin; and along portions of the male reproductive tract. Multiunit smooth muscle cells do not typically occur in the digestive tract.

Visceral smooth muscle cells are arranged in sheets or layers. Within each layer, adjacent muscle cells are connected by gap junctions. As a result, whenever one muscle cell contracts, the electrical impulse that triggered the contraction can travel to adjacent smooth muscle cells. For this reason, the contraction spreads in a wave that soon involves every smooth muscle cell in the layer. The initial stimulus may be the activation of a motor neuron that contacts one of the muscle cells in the region. But smooth muscle cells also contract or relax in response to chemicals, hormones, the local concentration of oxygen or carbon dioxide, or a physical factor such as extreme stretching or irritation.

Many visceral smooth muscle layers show rhythmic cycles of activity in the absence of neural stimulation. For example, these cycles are characteristic of the smooth muscle cells in the wall of the digestive tract, where **pacesetter cells** spontaneously trigger the contraction of entire muscular sheets. Visceral smooth muscle cells are found in the walls of the

digestive tract, the gallbladder, the urinary bladder, and many other internal organs.

Smooth Muscle Tone

Both multiunit and visceral smooth muscle tissues have a normal background level of activity, or smooth muscle tone. Neural, hormonal, or chemical factors can also stimulate smooth muscle relaxation, producing a decrease in muscle tone. For example, smooth muscle cells at the entrances to capillaries regulate the amount of blood flow into each vessel. If the tissue becomes starved for oxygen, the smooth muscle cells relax, allowing blood flow to increase and, hence, delivering additional oxygen. As conditions return to normal, the smooth muscle regains its normal muscle tone.

Table 10–3 summarizes how smooth muscle tissue differs from both skeletal and cardiac muscle tissues in structure and function.

Checkpoint

25. Identify the structural characteristics of smooth muscle tissue.
26. Which type of muscle tissue is least affected by changes in extracellular Ca^{2+} concentration during contraction?
27. Why can smooth muscle contract over a wider range of resting lengths than skeletal muscle can?

See the blue Answers tab at the back of the book.

10 Chapter Review

Study Outline

An Introduction to Muscle Tissue

1. The three types of muscle tissue are *skeletal muscle*, *cardiac muscle*, and *smooth muscle*.

10-1 The primary function of muscle tissue is to produce movement

2. Common properties of muscle tissue include **excitability**, **contractility**, **extensibility**, and **elasticity**.
3. **Skeletal muscles** attach to bones directly or indirectly. Their functions are to (1) produce skeletal movement, (2) maintain posture and body position, (3) support soft tissues, (4) guard body entrances and exits, (5) maintain body temperature, and (6) store nutrient reserves.

10-2 Skeletal muscle contains muscle tissue, connective tissues, blood vessels, and nerves

4. The entire muscle is covered by an **epimysium**. Bundles of muscle fibers (cells) are sheathed by a **perimysium**, and each muscle fiber is surrounded by an **endomysium**. At the ends of the muscle are tendons or aponeuroses that attach the muscle to bones. (Figure 10-1)
5. The perimysium and endomysium contain the blood vessels and nerves that supply the muscle fibers.

10-3 Skeletal muscle fibers are organized into repeating functional units that contain sliding filaments

6. A skeletal muscle fiber has a **sarcolemma** (plasma membrane), **sarcoplasm** (cytoplasm), and **sarcoplasmic reticulum (SR)**, similar to the smooth endoplasmic reticulum of other cells. **Transverse (T) tubules** and **myofibrils** aid in contraction. Filaments in a myofibril are organized into repeating functional units called **sarcomeres**. (Figures 10-2 to 10-6)
7. **Myofibrils** contain **myofilaments** called **thin filaments** and **thick filaments**. (Figures 10-2 to 10-6)
8. Thin filaments consist of **F-actin**, **nebulin**, **tropomyosin**, and **troponin**. Tropomyosin molecules cover **active sites** on the **G-actin** subunits that form the F-actin strand. Troponin binds to G-actin and tropomyosin and holds the tropomyosin in position. (Figure 10-7)
9. Thick filaments consist of a bundle of myosin molecules around a **titin** core. Each **myosin** molecule has a long **tail** and a globular **head**, which forms **cross-bridges** with a thin filament during contraction. In a resting muscle cell, tropomyosin prevents the myosin heads from attaching to active sites on G-actin. (Figure 10-7)
10. The relationship between thick and thin filaments changes as a muscle fiber contracts. (Figure 10-8)
11. During a contraction, the free end of a myofibril moves toward the end that is attached or fixed. This occurs in an intact skeletal muscle, when one end of the muscle (the *origin*) is fixed in

position during a contraction and the other end (the *insertion*) moves. (Figure 10-9)

10-4 Motor neurons stimulate skeletal muscle fibers to contract at the neuromuscular junction

12. Neurons and skeletal muscle fibers have **excitable membranes**, plasma membranes that can propagate electrical impulses, or action potentials.
13. A neuron controls the activity of a muscle fiber at a **neuromuscular junction (NMJ)**. (Spotlight Figure 10-10)
14. At the neuromuscular junction, when an **action potential** arrives at the neuron's **axon** (synaptic) **terminal**, **acetylcholine (ACh)** is released into the **synaptic cleft**. The binding of ACh to ACh receptor membrane channels on the motor end plate (and its junctional folds) of the muscle fiber leads to the generation of an action potential in the sarcolemma. (Spotlight Figure 10-10)
15. **Excitation-contraction coupling** occurs as the passage of an action potential along a T tubule triggers the release of Ca^{2+} from the cisternae of the SR at triads. (Spotlight Figure 10-11)
16. Release of Ca^{2+} initiates a **contraction cycle** of myosin head active-site exposure, cross-bridge formation, pivoting of the myosin head, cross-bridge detachment, and myosin reactivation. The calcium ions bind to troponin, which changes position and moves tropomyosin away from the active sites of actin. Cross-bridges of myosin heads then bind to actin. Next, each myosin head pivots, pulling the actin filament toward the center of the sarcomere, and then detaches. (Spotlight Figure 10-12)
17. When muscle cells contract, they create **tension** and pull on the attached tendons.
18. Acetylcholinesterase (AChE) breaks down ACh and limits the duration of muscle stimulation. (Figure 10-13)

10-5 Muscle fibers produce different amounts of tension depending on sarcomere length and frequency of stimulation

19. The amount of tension produced by a muscle fiber depends on the number of cross-bridges formed.
20. Skeletal muscle fibers can contract most forcefully when stimulated over a narrow range of resting lengths. (Figure 10-14)
21. A **twitch** is a cycle of contraction and relaxation produced by a single stimulus. (Figure 10-15)

22. Repeated stimulation at a slow rate produces **treppe**, a progressive increase in twitch tension. (*Figure 10–16*)
23. Repeated stimulation before the relaxation phase ends may produce **wave summation**, in which one twitch is added to another; **incomplete tetanus**, in which tension peaks and falls at intermediate stimulus rates; or **complete tetanus**, in which the relaxation phase is eliminated by very rapid stimuli. (*Figure 10–16*)

10-6 Skeletal muscles produce increased tension by recruiting additional motor units

24. The number and size of a muscle's motor units determine how precisely controlled its movements are. (*Figure 10–17*)
25. Resting **muscle tone** stabilizes bones and joints.
26. Most activities generally include both **isotonic contractions** (in which the tension in a muscle rises and the length of the muscle changes) and **isometric contractions** (in which tension rises, but the length of the muscle stays the same). There are two types of isotonic contractions: **concentric** and **eccentric**. (*Figure 10–18*)
27. Load and speed of contraction are inversely related. (*Figure 10–19*)
28. The return to resting length after a contraction may involve elastic forces, opposing muscle contractions, and gravity.

10-7 To maintain regular muscle fiber activity, energy and recovery are required

29. Muscle contractions require large amounts of energy. (*Table 10–1*)
30. **Creatine phosphate (CP)** can release stored energy to convert ADP to ATP. (*Table 10–1*)
31. At rest or at moderate levels of activity, **aerobic metabolism** (the citric acid cycle and the electron transport chain in the mitochondria) can provide most of the ATP needed to support muscle contractions.
32. At peak levels of activity, the muscle cell relies heavily on **anaerobic metabolism (glycolysis)** to generate ATP, because the mitochondria cannot obtain enough oxygen to meet the existing ATP demands.
33. As muscular activity changes, the pattern of energy production and use changes. (*Figure 10–20*)
34. A fatigued muscle can no longer contract, because of a drop in pH due to the buildup of hydrogen ions, the exhaustion of energy resources, or other factors.
35. The **recovery period** begins immediately after a period of muscle activity and continues until conditions inside the muscle have returned to pre-exertion levels. The **oxygen debt**, or **excess postexercise oxygen consumption (EPOC)**, created during exercise is the amount of oxygen required during the recovery period to restore the muscle to its normal condition.
36. Circulating hormones may alter metabolic activities in skeletal muscle fibers.

10-8 Muscle performance depends on muscle fiber type and physical conditioning

37. The three types of skeletal muscle fibers are **fast fibers**, **slow fibers**, and **intermediate fibers**. (*Figure 10–21; Table 10–2*)

38. Fast fibers, which are large in diameter, contain densely packed myofibrils, large glycogen reserves, and relatively few mitochondria. They produce rapid and powerful contractions of relatively brief duration. (*Figure 10–21*)
39. Slow fibers are about half the diameter of fast fibers and take three times as long to contract after stimulation. Specializations such as abundant mitochondria, an extensive capillary supply, and high concentrations of **myoglobin** enable slow fibers to continue contracting for extended periods. (*Figure 10–21*)
40. Intermediate fibers are very similar to fast fibers, but they have a greater resistance to fatigue.
41. Muscles dominated by fast fibers appear pale and are known as **white muscles**.
42. Muscles dominated by slow fibers are rich in myoglobin, appear red, and are known as **red muscles**.
43. Training to develop anaerobic endurance can lead to **hypertrophy** (enlargement) of the stimulated muscles.
44. With advanced age, skeletal muscles undergo **fibrosis**, the tolerance for exercise decreases, and repair of injuries slows.
45. **Anaerobic endurance** is the time over which muscular contractions can be sustained by glycolysis and reserves of ATP and CP.
46. **Aerobic endurance** is the time over which a muscle can continue to contract while supported by mitochondrial activities.

10-9 Cardiac muscle tissue, found in the heart, produces coordinated and automatic contractions

47. **Cardiac muscle tissue** is located only in the heart. **Cardiac muscle cells** are small; have one centrally located nucleus; have short, broad T tubules; and are dependent on aerobic metabolism. **Intercalated discs** bind the sarcolemmas of neighboring cardiac muscle cells. (*Figure 10–22; Table 10–3*)
48. Cardiac muscle cells contract without neural stimulation (**automaticity**), and their contractions last longer than those of skeletal muscle.
49. Because cardiac muscle twitches do not exhibit wave summation, cardiac muscle tissue cannot produce tetanic contractions.

10-10 Smooth muscle tissue contracts to move substances within internal passageways

50. **Smooth muscle tissue** is nonstriated, involuntary muscle tissue.
51. Smooth muscle cells lack sarcomeres and the resulting striations. The thin filaments are anchored to **dense bodies**. (*Figure 10–23; Table 10–3*)
52. Smooth muscle contracts when calcium ions interact with **calmodulin**, which activates **myosin light chain kinase**.
53. Smooth muscle functions over a wide range of lengths (**plasticity**).
54. In **multiunit smooth muscle cells**, each smooth muscle cell acts relatively independently of other smooth muscle cells in the organ. **Visceral smooth muscle cells** are not always innervated by motor neurons. Neurons that innervate smooth muscle cells are not under voluntary control.

Review Questions

See the blue Answers tab at the back of the book.

LEVEL 1 Reviewing Facts and Terms

1. Identify the structures in the following figure.

- | | |
|-----------|-----------|
| (a) _____ | (b) _____ |
| (c) _____ | (d) _____ |
| (e) _____ | (f) _____ |
| (g) _____ | (h) _____ |

- The connective tissue coverings of a skeletal muscle, listed from superficial to deep, are (a) endomysium, perimysium, and epimysium, (b) endomysium, epimysium, and perimysium, (c) epimysium, endomysium, and perimysium, (d) epimysium, perimysium, and endomysium.
- Troponin and tropomyosin are components of the (a) thin filaments of myofibrils, (b) thick filaments of myofibrils, (c) sarcoplasm, (d) endomysium, (e) sarcolemma.
- The detachment of the myosin cross-bridges is directly triggered by (a) the repolarization of T tubules, (b) the attachment of ATP to myosin heads, (c) the hydrolysis of ATP, (d) calcium ions.
- All of the following are components of the endomysium, *except* (a) myosatellite cells, (b) capillary networks, (c) nerve fibers, (d) muscle fibers.
- A muscle in which the peak tension increases with each successive stimulus delivered shortly after the completion of the relaxation phase of the preceding twitch is said to be in (a) treppe, (b) incomplete tetanus, (c) complete tetanus, (d) wave summation.
- Which of the following statements about fast skeletal muscle fibers is *not* correct? (a) Muscles dominated by fast fibers are known as white muscles. (b) The myoglobin content is low. (c) The glycolytic enzyme concentration in sarcoplasm is high. (d) They feel fatigue easily. (e) They have more mitochondria and a more extensive capillary supply than slow fibers.
- The twitches of which skeletal muscle have the shortest duration? (a) gastrocnemius muscle, (b) soleus muscle, (c) eye muscle, (d) thigh muscle.
- List the three types of muscle tissue in the body.
- What three layers of connective tissue are part of each muscle? What functional role does each layer play?
- The _____ contains vesicles filled with acetylcholine. (a) axon terminal, (b) motor end plate, (c) neuromuscular junction, (d) synaptic cleft, (e) transverse tubule.
- What structural feature of a skeletal muscle fiber propagates action potentials into the interior of the cell?
- What five interlocking steps are involved in the contraction process?
- What two factors affect the amount of tension produced when a skeletal muscle contracts?

- What is the meaning of the term recruitment?
- What is the difference between white and red muscles?
- Which structures allow transmission of contractile forces in smooth muscle tissue?

LEVEL 2 Reviewing Concepts

- An activity that would require aerobic endurance is (a) resistance training, (b) brisk walking, (c) a 50-meter dash, (d) weightlifting.
- Multiunit smooth muscle cells are found in the (a) walls of large arteries, (b) walls of the digestive tract, (c) gall bladder, (d) urinary bladder.
- During relaxation, muscles return to their original length because of all the following *except* (a) actin and myosin actively pushing away from one another, (b) the contraction of opposing muscles, (c) the pull of gravity, (d) the elastic nature of the sarcolemma, (e) elastic forces.
- According to the length-tension relationship, (a) longer muscles can generate more tension than shorter muscles, (b) the greater the zone of overlap in the sarcomere, the greater the tension the muscle can develop, (c) the greatest tension is achieved in sarcomeres where actin and myosin initially do not overlap, (d) there is an optimum range of actin and myosin overlap that will produce the greatest amount of tension, (e) both b and d are correct.
- For each portion of a myogram tracing a twitch in a stimulated calf muscle fiber, describe the events that occur within the muscle fiber.
- How can hormones play a role in adjusting metabolic activities in skeletal muscle fibers?
- Compare cardiac and skeletal muscles in terms of muscle fatigue.
- Atracurium is a drug that blocks the binding of ACh to ACh receptors. Give an example of a site where such binding normally occurs and predict the physiological effect of this drug.
- Explain why a murder victim's time of death can be estimated according to the flexibility or rigidity of the body.
- When the muscle tension exceeds the load and the muscle shortens, we have a(n) (a) isometric contraction, (b) isotonic concentric contraction, (c) isotonic eccentric contraction, (d) incomplete tetanus, (e) complete tetanus.

LEVEL 3 Critical Thinking and Clinical Applications

- Many potent insecticides contain toxins, called organophosphates, that interfere with the action of the enzyme acetylcholinesterase. Ivan is using an insecticide containing organophosphates and is very careless. Because he does not use gloves or a dust mask, he absorbs some of the chemical through his skin and inhales a large amount as well. What signs are expected in Ivan as a result of organophosphate poisoning?
- Linda's father has an apparent heart attack and is rushed to the emergency room of the local hospital. The doctor on call tells her that he has ordered some blood work and that he will know if her father actually had a heart attack by looking at the blood levels of CK and cardiac troponin. Why would knowing the level of CK and cardiac troponin help to indicate if a person had a heart attack?
- Georgia will be running a marathon for the first time, and she is keen on performing well. What are some of the things that she should keep in mind in order to complete the run safely and with a sufficient energy supply?

CLINICAL CASE Wrap-Up Keep on Keepin' on

Rhetta is struggling with myasthenia gravis, a disease of the neuromuscular junction (NMJ). In people with this autoimmune disease, the immune system mistakenly makes antibodies that damage the acetylcholine (ACh) receptor sites on the surface of the motor end plates of skeletal muscle fibers. The ACh that is released by the axon terminal of the motor neuron cannot find enough intact ACh receptors on which to bind. For this reason, the muscle fiber membrane permeability to sodium ions does not change enough, and the cascade of events leading to muscular contraction is feeble. The result is weakness and fatigability. This weakness improves with rest as the ACh store is built up again. Often the muscles of the eyes, including the eyelids, and other facial muscles are affected first. All voluntary, skeletal muscles can be affected.

The neurologist injected Rhetta with Tensilon (edrophonium chloride), a short-acting acetylcholinesterase (AChE) inhibitor. The drug blocks AChE, the enzyme that breaks down ACh, and so prolongs muscle stimulation. Sadly, the dramatic effects, such as suddenly being able to open and move both eyes, are short lived. There are, however, many treatments available for myasthenia gravis, including long-acting AChE inhibitors.

Rhetta responded well to treatment and was able to resume playing with her band.

1. How would a drug that inhibits AChE make a myasthenia gravis patient stronger?
2. Would myasthenia gravis affect Rhetta's heart muscle? Explain.

See the blue Answers tab at the back of the book.

10

Related Clinical Terms

botulism: A severe, potentially fatal paralysis of skeletal muscles, resulting from the consumption of a bacterial toxin.

Duchenne muscular dystrophy (DMD): One of the most common and best understood of the muscular dystrophies.

fibromyalgia: A chronic disorder characterized by widespread musculoskeletal pain, fatigue, and localized tenderness.

muscular dystrophies: A varied collection of inherited diseases that produce progressive muscle weakness and deterioration.

myasthenia gravis: A general muscular weakness resulting from a reduction in the number of ACh receptors on the motor end plate.

myopathy: Disease of muscle tissue.

RICE (rest, ice, compression, and elevation): Acronym for the standard treatment for muscle injuries, bruises, strains, and sprains.

The Muscular System

Learning Outcomes

These Learning Outcomes correspond by number to this chapter's sections and indicate what you should be able to do after completing the chapter.

- 11-1 ■ Describe the arrangement of fascicles in the various types of muscles and explain the resulting functional differences.
- 11-2 ■ Describe the classes of levers and explain how they make muscles more efficient.
- 11-3 ■ Predict the actions of a muscle based on its origin and insertion and explain how muscles interact to produce or oppose movements.
- 11-4 ■ Explain how the name of a muscle can help identify its location, appearance, or function.
- 11-5 ■ Compare and contrast the axial and appendicular muscles.
- 11-6 ■ Identify the principal axial muscles of the body, plus their origins, insertions, actions, and innervation.
- 11-7 ■ Identify the principal appendicular muscles of the body, plus their origins, insertions, actions, and innervation, and compare the major functional differences between the upper and lower limbs.
- 11-8 ■ Explain the functional relationship between the muscular system and other body systems and explain the role of exercise in producing various responses in other body systems.

CLINICAL CASE

Downward-Facing Dog

“Breathe and do what *you* can do,” the instructor called out to the class in soothing tones. Rick concentrated on his yoga pose. He’d been coming to class with the encouragement of his nurse practitioner. “I think yoga could help you move and feel better. Your arthritis medications can only do so much for you. Give yoga the old college try. Let’s see you again in 3 months,” she urged.

Rick was impressed with the gentle practice of yoga. The first week in class his body felt stiff and sore from his arthritic joints. But he stayed with the program

and practiced a little between classes. Three months later, he could stretch his arms overhead and balance on one foot for a few seconds in tree pose. His leg muscles felt stronger as he stepped sideways into warrior pose. His next challenge was to tackle the most famous yoga pose of all, downward-facing dog. He thought that he might be up to trying it. Slow and easy, he told himself. **What will the nurse practitioner test on Rick’s return visit?**

To find out, turn to the Clinical Case Wrap-Up at the end of the chapter.

11

An Introduction to the Muscular System

In this chapter we describe the gross anatomy of the muscular system and consider functional relationships between muscles and bones of the body. Most skeletal muscle fibers contract at similar rates and shorten to the same degree, but variations in their microscopic and macroscopic organization can dramatically affect the power, range, and speed of movement produced when a whole muscle contracts.

11-1 Fascicle arrangement is correlated with muscle power and range of motion

Learning Outcome Describe the arrangement of fascicles in the various types of muscles and explain the resulting functional differences.

Muscle fibers in a skeletal muscle form bundles called *fascicles* (FAS-ih-kulz). The muscle fibers in a single fascicle are parallel, but the arrangement of fascicles in skeletal muscles can vary, as can the relationship between the fascicles and the associated tendon. Based on the patterns of fascicle arrangement, we can classify skeletal muscles as *parallel muscles*, *convergent muscles*, *pennate muscles*, and *circular muscles* (Figure 11-1).

Parallel Muscles

In a **parallel muscle**, the fascicles are parallel to the long axis of the muscle. Most of the skeletal muscles in the body are parallel muscles. Some are flat bands with broad attachments (*aponeuroses*; ap-ō-nū-RŌ-sēz) at each end. Others are plump and cylindrical, with tendons at one or both ends. Such a muscle is spindle shaped, with a central **body**, also known as the *belly*. For example, the *biceps brachii* of the arm is a parallel muscle with a central body (Figure 11-1a). When a parallel muscle contracts, it shortens and gets larger in diameter. When the elbow flexes, there is a corresponding bulge on the

anterior arm surface resulting from the contracting biceps brachii muscle. Other parallel muscles include the *rectus abdominis* (Figure 11-1b) and *supinator* (Figure 11-1c).

A skeletal muscle fiber can contract until it has shortened about 30%. The entire parallel muscle shortens by this amount when its fibers contract together because these fibers are parallel to the long axis of the muscle. Thus, if the muscle is 10 cm (3.9 in.) long and one end is held in place, the other end will move 3 cm when the muscle contracts. The tension developed during this contraction depends on the total number of myofibrils the muscle contains.

Convergent Muscles

In a **convergent muscle**, muscle fascicles extending over a broad area come together, or converge, on a common attachment site. The muscle may pull on a tendon, an aponeurosis, or a slender band of collagen fibers known as a **raphe** (RĀ-fē; seam). The muscle fibers typically spread out, like a fan or a broad triangle, with a tendon at the apex. Examples include the prominent *pectoralis muscles* of the chest (Figure 11-1d).

A convergent muscle can adapt to different activities because the stimulation of different portions of the muscle can change the direction it pulls. However, when the entire muscle contracts, the muscle fibers do not pull as hard on the attachment site as would a parallel muscle of the same size. Why? The reason is that convergent muscle fibers pull in different directions, rather than all pulling in the same direction as in parallel muscles.

Pennate Muscles

In a **pennate muscle** (PEN-āt; *penna*, feather), the fascicles form a common angle with the tendon. Because the muscle fibers pull at an angle, contracting pennate muscles do not move their tendons as far as parallel muscles do. But a

Figure 11–1 Muscle Types Based on Fascicle Arrangement.

pennate muscle contains more muscle fibers—and thus more myofibrils—than does a parallel muscle of the same size. For this reason, the pennate muscle produces more tension.

There are three types of pennate muscles, depending on the arrangement of the fascicles with the tendon. If all the muscle fascicles are on the same side of the tendon, the pennate muscle is *unipennate*. The *extensor digitorum*, a forearm muscle that extends the finger joints, is unipennate (**Figure 11–1e**). More commonly, a pennate muscle has fascicles on both sides of a central tendon. Such a muscle is called *bipennate*. The *rectus femoris*, a prominent muscle that extends the knee, is bipennate (**Figure 11–1f**). If the tendon

branches within a pennate muscle, the muscle is said to be *multipennate*. The triangular *deltoid* of the shoulder is multipennate (**Figure 11–1g**).

Circular Muscles

In a **circular muscle**, or **sphincter** (SFINK-ter), the fascicles are concentrically arranged around an opening. When the muscle contracts, the diameter of the opening becomes smaller. Circular muscles surround body openings or hollow organs and act as valves in the digestive and urinary tracts. An example is the *orbicularis oris* of the mouth (**Figure 11–1h**).

✓ Checkpoint

1. Based on patterns of fascicle arrangement, name the four types of skeletal muscle.
2. Why does a pennate muscle generate more tension than does a parallel muscle of the same size?
3. Which type of fascicle arrangement is expected in a muscle guarding the anal opening between the large intestine and the exterior?

See the blue Answers tab at the back of the book.

11-2 The use of bones as levers increases muscle efficiency

Learning Outcome Describe the classes of levers and explain how they make muscles more efficient.

Skeletal muscles do not work in isolation. For muscles attached to the skeleton, the nature and site of their connections determine the force, speed, and range of the movement they produce. These characteristics are interdependent, and the relationships can explain a great deal about the general organization of the muscular and skeletal systems.

Attaching the muscle to a lever can modify the force, speed, or direction of movement produced by muscle contraction. A *lever* is a rigid structure—such as a board, a crowbar, or a bone—that moves on a fixed point called a *fulcrum*. A lever moves when pressure, called an *applied force*, is sufficient to overcome any load that would otherwise oppose or prevent such movement.

In the body, each bone is a lever and each joint is a fulcrum. Muscles provide the applied force. The load can vary from the weight of an object held in the hand to the weight of a limb or the weight of the entire body, depending on the situation. The important thing about levers is that they can change (1) the direction of an applied force, (2) the distance and speed of movement produced by an applied force, and (3) the effective strength of an applied force.

There are three classes of levers. A lever is classified according to the relative position of three elements: applied force, fulcrum, and load. Regardless of the class of lever, all follow the same mechanical principles: A mechanical advantage occurs when the applied force is farther from the fulcrum than the load. A mechanical disadvantage occurs when the applied force is closer to the load than the fulcrum.

We find examples of each class of lever in the human body (**Figure 11-2**). A pry bar or crowbar is an example of a **first-class lever**. In such a lever, the fulcrum (F) lies between the applied force (AF) and the load (L). We can describe the positions as L–F–AF. The body has few first-class levers. One, involved with extension of the neck and lifting the head, is shown in **Figure 11-2a**.

A familiar example of a **second-class lever** is a loaded wheelbarrow. The load lies between the applied force and the fulcrum (**Figure 11-2b**). The weight is the load, and the upward lift on the handle is the applied force. We can describe the positions as F–L–AF. In this arrangement, a small force can move a larger weight because the force is always farther from the fulcrum than the load is. That is, the effective force is increased. Notice, however, that when a force moves the handle, the load moves more slowly and covers a shorter distance. In other words, the effective force is increased at the expense of speed and distance. The body has few second-class levers. Ankle extension (plantar flexion) by the calf muscles involves a second-class lever (**Figure 11-2b**).

In a **third-class lever**, such as a pair of tongs, the applied force is between the load and the fulcrum (**Figure 11-2c**). We can describe the positions as F–AF–L. Third-class levers are the most common levers in the body. The effect is the reverse of that for a second-class lever: Speed and distance traveled are increased at the expense of effective force.

Not every muscle is part of a lever system, but levers provide speed and versatility far in excess of what we would predict for the body on the basis of muscle physiology alone.

✓ Checkpoint

4. Define a lever and describe the three classes of levers.
5. The joint between the occipital bone of the skull and the first cervical vertebra (atlas) is a part of which class of lever?

See the blue Answers tab at the back of the book.

11-3 The origins and insertions of muscles determine their actions

Learning Outcome Predict the actions of a muscle based on its origin and insertion and explain how muscles interact to produce or oppose movements.

To understand the actions of skeletal muscles, we need to understand where they are connected to the bones that act as levers and which joints (articulations) they cross.

Origins and Insertions

In Chapter 10 we noted that when both ends of a myofibril are free to move, the ends move toward the center during a contraction. In the body, the ends of a skeletal muscle are always attached to other structures that limit their movement. In most cases one end is fixed in position, and during a contraction the other end moves toward the fixed end. The less movable end is called the **origin** of the muscle. The more movable end is called the **insertion** of the muscle. The origin is typically proximal to the insertion. Almost all skeletal muscles either originate or insert on the skeleton.

Figure 11–2 The Three Classes of Levers.**a First-class lever**

The fulcrum (F) lies between the applied force (AF) and the load (L).

Example: Pry bar

**b Second-class lever**

The load (L) lies between the applied force (AF) and the fulcrum (F).

Example: Wheelbarrow

**c Third-class lever**

The force (F) is applied between the load (L) and the fulcrum (F).

Example: Tongs

The decision as to which end is the origin and which is the insertion is usually based on movement from the anatomical position. As an example, consider the *gastrocnemius*, a calf muscle that extends from the distal portion of the femur to the calcaneus. As **Figure 11–2b** shows, when the gastrocnemius contracts, it pulls the calcaneus toward the knee. As a result, we say that the gastrocnemius has its origin at the femur and its insertion at the calcaneus. Part of

the fun of studying the muscular system is thinking about the muscles involved. As a result, laboratory activities focusing on muscle actions are often like disorganized exercise classes.

When we cannot easily determine the origins and insertions based on movement from the anatomical position, we have other rules to use. If a muscle extends between a broad aponeurosis and a narrow tendon, the aponeurosis is the

origin and the tendon is the insertion. If several tendons are at one end and just one is at the other, the muscle has multiple origins and a single insertion. However, these simple rules cannot cover every situation. Knowing which end is the origin and which is the insertion is ultimately less important than knowing where the two ends attach and what the muscle accomplishes when it contracts.

Most muscles originate at a bone, but some originate at a connective tissue sheath or band. Examples of these sheaths or bands include *intermuscular septa* (components of the deep fascia that may separate adjacent skeletal muscles), *tendinous inscriptions* that join muscle fibers to form long muscles such as the *rectus abdominis*, the interosseous membranes of the forearm or leg, and the fibrous sheet that spans the obturator foramen of the pelvis.

Actions

When a muscle contracts, it produces a specific **action**, or movement. As introduced in Chapter 9, when a muscle moves a portion of the skeleton, that movement may involve flexion, extension, adduction, abduction, protraction, retraction, elevation, depression, rotation, circumduction, pronation, supination, inversion, eversion, lateral flexion, opposition, or reposition. (Before proceeding, you may want to review the discussions of planes of motion as well as **Spotlight Figure 9-2** and **Figures 9-3** to **9-5**.)

We can describe actions in two ways, one focused on the bone and one on the joint. The first way describes actions in terms of the bone or region affected. For example, we say a muscle such as the biceps brachii performs “flexion of the forearm.” However, specialists such as kinesiologists and physical therapists increasingly use the second way, which identifies the joint involved. In this approach, we say the action of the biceps brachii is “flexion at (or of) the elbow.” Examples of muscle action are presented in **Spotlight Figure 11-3**.

In complex movements, muscles commonly work in groups rather than individually. Their cooperation improves the efficiency of a particular movement. For example, large muscles of the limbs produce flexion or extension over an extended range of motion. These muscles cannot produce powerful movements at full extension due to the positions of the articulating bones, but they are usually paired with one or more smaller muscles that provide assistance until the larger muscle can perform at maximum efficiency. At the start of the movement, the smaller muscle produces maximum tension, while the larger muscle produces minimum tension. The importance of the smaller “assistant” decreases as the movement proceeds and the effectiveness of the primary muscle increases.

To describe how muscles work together, we can use the following four functional types: agonist, antagonist, synergist, and fixator.

- An **agonist**, or **prime mover**, is a muscle whose contraction is mostly responsible for producing a particular movement. The biceps brachii is an agonist that produces flexion at the elbow.
- An **antagonist** is a muscle whose action opposes that of a particular agonist. The *triceps brachii* is an agonist that extends the elbow. For this reason, it is an antagonist of the biceps brachii. Likewise, the biceps brachii is an antagonist of the triceps brachii.

Agonists and antagonists are functional opposites. If one produces flexion, the other produces extension. When an agonist contracts to produce a particular movement, the corresponding antagonist is stretched, but it usually does not relax completely. Instead, it contracts eccentrically, with just enough tension to control the speed of the movement and ensure its smoothness.

You may find it easiest to learn about muscles in agonist–antagonist pairs (flexors–extensors, abductors–adductors) that act at a specific joint. This method highlights the functions of the muscles involved, and it can help organize the information into a logical framework. The tables in this chapter are arranged to support such an approach.

- When a **synergist** (*syn-*, together + *ergon*, work) contracts, it helps a larger agonist work efficiently. Synergists may provide additional pull near the insertion or may stabilize the point of origin. Their importance in assisting a particular movement may change as the movement progresses. In many cases, they are most useful at the start, when the agonist is stretched and unable to develop maximum tension. For example, the *latissimus dorsi* is a large trunk muscle that extends, adducts, and medially rotates the arm at the shoulder joint. A much smaller muscle, the *teres* (TER-ēz) *major*, assists in starting such movements when the shoulder joint is at full flexion.
- A **fixator** is a synergist that assists an agonist by preventing movement at another joint, thereby stabilizing the origin of the agonist. Recall that the biceps brachii is an agonist that produces flexion at the elbow. It has two tendons that originate on the scapula and one that inserts on the radius. During flexion, the trapezius and rhomboid act as fixators by stabilizing and preventing the movement of the scapula.

Checkpoint

6. The **gracilis** attaches to the anterior surface of the tibia at one end and to the pubis and ischium of the pelvis at the other. When the muscle contracts, flexion occurs at the hip. Which attachment point is considered the muscle's origin?
7. Muscle A abducts the humerus, and muscle B adducts the humerus. What is the relationship between these two muscles?
8. Define the term **synergist** as it relates to muscle action.

See the blue Answers tab at the back of the book.

Media resource available for this topic: A&P Flix: Origins, Insertions, Actions, Innervations

The action produced by a muscle at any one joint is largely dependent upon the structure of the joint and the location of the insertion of the muscle relative to the axis of movement at the joint. The direction, or geometric paths, of the action produced by a muscle—called *lines of action*—is often represented by an arrow (or more than one arrow in fan-shaped muscles).

Flexion and Extension

At joints that permit flexion and extension, muscles whose lines of action cross the anterior side of a joint are flexors of that joint, and muscles whose lines of action cross the posterior side of a joint are extensors of that joint.

Abduction and Adduction

At joints that permit adduction and abduction, muscles whose lines of action cross the medial side of a joint are adductors of that joint, and muscles whose lines of action cross the lateral side of a joint are abductors of that joint.

Medial and Lateral Rotation

At joints that permit rotation, movement or turning of the body part occurs around its axis. The shoulder joint is a ball-and-socket joint that permits rotation. The subscapularis has lines of action that cross the anterior aspect of the shoulder joint. When the subscapularis contracts it produces medial rotation at the joint. The teres minor has lines of action that cross the posterior aspect of the shoulder joint. When the teres minor contracts, it produces lateral rotation at the shoulder.

11-4 Descriptive terms are used to name skeletal muscles

Learning Outcome Explain how the name of a muscle can help identify its location, appearance, or function.

The human body has approximately 700 muscles. You do not need to learn every one of their names, but you will have to become familiar with many of them. Fortunately, the names anatomists assigned to the muscles include descriptive terms that can help you remember the names and identify the muscles. When you are faced with a new muscle name, it is helpful to first identify the descriptive portions of the name.

The name of a muscle may include descriptive information about its region of the body; position, direction, and fascicle arrangement; structural characteristics; and action. **Table 11-1** includes a useful summary of muscle terminology.

Region of the Body

Regional terms are most common as modifiers that help identify individual muscles. In a few cases, a muscle is such a prominent feature of a body region that a name referring to the region alone will identify it. Examples include the *temporalis* of the head and the *brachialis* (brā-kē-A-lis) of the arm (**Figure 11-4a**).

Table 11-1 Muscle Terminology

Terms Indicating Specific Regions of the Body	Terms Indicating Position, Direction, or Fascicle Arrangement	Terms Indicating Structural Characteristics of the Muscle	Terms Indicating Actions
Abdominal (abdomen)	Anterior (front)	NATURE OF ORIGIN	GENERAL
Ancon (elbow)	External (on the outside)	Biceps (two heads)	Abductor (movement away)
Auricular (ear)	Extrinsic (outside the structure)	Triceps (three heads)	Adductor (movement toward)
Brachial (arm)	Inferior (below)	Quadriceps (four heads)	Depressor (lowering movement)
Capitis (head)	Internal (away from the surface)		Extensor (straightening movement)
Carpi (wrist)	Intrinsic (within the structure)	SHAPE	Flexor (bending movement)
Cervicis (neck)	Lateral (on the side)	Deltoid (triangle)	Levator (raising movement)
Coccygeal (coccyx)	Medial (middle)	Orbicularis (circle)	Pronator (turning into prone position)
Costal (rib)	Oblique (slanting)	Pectinate (comblike)	Supinator (turning into supine position)
Cutaneous (skin)	Posterior (back)	Piriformis (pear shaped)	Tensor (tensing movement)
Femoris (thigh)	Profundus (deep)	Platysma (flat plate)	
Glossal (tongue)	Rectus (straight)	Pyramidal (pyramid)	SPECIFIC
Hallux (great toe)	Superficial (toward the surface)	Rhomboid (parallelogram)	Buccinator (trumpeter)
Ilium (groin)	Superior (toward the head)	Serratus (serrated)	Risorius (laugher)
Inguinal (groin)	Transverse (crosswise)	Splenius (bandage)	Sartorius (like a tailor)
Lumbar (lumbar region)		Teres (round and long)	
Nasalis (nose)		Trapezius (trapezoid)	
Nuchal (back of neck)		OTHER STRIKING FEATURES	
Ocular (eye)		Alba (white)	
Oris (mouth)		Brevis (short)	
Palpebra (eyelid)		Gracilis (slender)	
Pollex (thumb)		Latae (wide)	
Popliteal (posterior to knee)		Latissimus (widest)	
Psoas (loin)		Longissimus (longest)	
Radial (forearm)		Longus (long)	
Scapular (scapula)		Magnus (large)	
Temporal (temple)		Major (larger)	
Thoracic (thorax)		Maximus (largest)	
Tibial (tibia; shin)		Minimus (smallest)	
Ulnar (ulna)		Minor (smaller)	
		Vastus (great)	

Figure 11–4 An Overview of the Major Skeletal Muscles.

Figure 11–4 An Overview of the Major Skeletal Muscles. (*continued*)

Position, Direction, or Fascicle Arrangement

Muscles visible at the body surface are often called **externus** or **superficialis**. Deeper muscles are termed **internus** or **profundus**. Superficial muscles that position or stabilize an organ are called **extrinsic**. Muscles located entirely within an organ are **intrinsic**.

Muscle names may be directional indicators. For example, **transversus** and **oblique** indicate muscles that run across (transversus) or at a slanting (oblique) angle to the longitudinal axis of the body.

A muscle name may refer to the orientation of the muscle fascicles within a particular skeletal muscle. **Rectus** means “straight,” and most rectus muscles have fascicles that run along the longitudinal axis of the muscle. Because we have several rectus muscles, the name typically includes a second term that refers to a precise region of the body. For example, the *rectus abdominis* of the abdomen is an axial muscle that has straight fascicles that run along its long axis. However, in the case of the *rectus femoris*, *rectus* refers to “straight muscle of the thigh” and not to its fascicles (which are bipennate).

Structural Characteristics

Some muscles are named after distinctive structural features, such as multiple tendons, shape, and size.

Origin and Insertion

The biceps brachii, for example, is named after its origin. It has two tendons of origin (*bi-*, two + *caput*, head). Similarly, the triceps brachii has three, and the *quadriceps femoris* has four.

Many muscle names include terms for body places that tell you the specific origin and insertion of each muscle. In such cases, the first part of the name indicates the origin, the second part the insertion. The *genioglossus*, for example, originates at the chin (*geneion*) and inserts in the tongue (*glossus*). The names may be long and difficult to pronounce, but **Table 11–1** and the anatomical terms introduced in Chapter 1 can help you identify and remember them.

Shape and Size

Shape is sometimes an important clue to the name of a muscle. For example, the *trapezius* (tra-PĒ-zē-us), *deltoid*, *rhomboid* (ROM-boyd), and *orbicularis* (or-bik-ū-LĀ-ris) look like a trapezoid, a triangle (like the Greek letter delta, Δ), a rhomboid (lopsided rectangle), and a circle, respectively.

Many terms refer to muscle size. Long muscles are called **longus** (long) or **longissimus** (longest). **Teres** muscles are both long and round. Short muscles are called **brevis**. Large ones are called **magnus** (big), **major** (bigger), or **maximus** (biggest). Small ones are called **minor** (smaller) or **minimus** (smallest).

Action

Many muscles are named *flexor*, *extensor*, *pronator*, *abductor*, *adductor*, and *rotator* (**Spotlight Figure 11–3**). These are such

common actions that the names almost always include other clues as to the appearance or location of the muscle. For example, the *extensor carpi radialis longus* is a long muscle along the radial (lateral) border of the forearm. When it contracts, its primary function is extension at the carpus (wrist).

A few muscles are named after the specific movements associated with special occupations or habits. The *buccinator* (BUK-si-nā-tor) on the face compresses the cheeks—when, for example, you purse your lips and blow forcefully. *Buccinator* translates as “trumpeter.” Another facial muscle, the *risorius* (ri-SOR-ē-us), was supposedly named after the mood expressed: The Latin word *risor* means “one who laughs.” However, a more appropriate description for the effect would be “a grimace.” The *sartorius* (sar-TOR-ē-us), the longest in the body, is active when you cross your legs. Before sewing machines were invented, a tailor would sit on the floor cross-legged. The name of this muscle was derived from *sartor*, the Latin word for “tailor.”

Checkpoint

- Identify the kinds of descriptive information used to name skeletal muscles.
- What does the name *flexor carpi radialis longus* indicate about this muscle?

See the blue Answers tab at the back of the book.

11-5 Axial muscles position the axial skeleton, and appendicular muscles support and move the appendicular skeleton

Learning Outcome Compare and contrast the axial and appendicular muscles.

The separation of the skeletal system into axial and appendicular divisions serves as a useful guideline for subdividing the muscular system:

- The **axial muscles** arise on the axial skeleton. This category includes approximately 60% of the skeletal muscles in the body. They position the head and vertebral column; move the rib cage, which assists the movements that make breathing possible; and form the pelvic floor.
- The **appendicular muscles** stabilize or move structures of the appendicular skeleton. Forty percent of skeletal muscles are appendicular muscles, including those that move and support the pectoral (shoulder) and pelvic girdles and the upper and lower limbs.

Figure 11–4 provides an overview of the major axial and appendicular muscles of the human body. These are superficial muscles, which tend to be rather large. The superficial muscles cover deeper, smaller muscles that we cannot see unless the overlying muscles are removed, or *reflected*—that is, cut and pulled out of the way. Later figures that show deep

muscles in specific regions will indicate whether superficial muscles have been reflected.

In the next two sections, we give examples of axial muscles (Section 11-6) and appendicular muscles (Section 11-7). Pay attention to patterns of origin, insertion, and action. In the figures in this chapter, some bony and cartilaginous landmarks are also labeled to provide orientation.

The tables that follow also contain information about the innervation of the individual muscles. **Innervation** is the distribution of nerves to a region or organ. The tables indicate the nerves that control each muscle. Many of the muscles of the head and neck are innervated by *cranial nerves*, which originate at the brain and pass through the foramina of the skull. In addition, *spinal nerves* are connected to the spinal cord and pass through the intervertebral foramina. For example, spinal nerve L₁ passes between vertebrae L₁ and L₂. Spinal nerves may form a complex network called a *plexus* after exiting the spinal cord. One branch of this network may contain axons from several spinal nerves. Many tables identify the spinal nerves involved as well as the names of their specific branches.

Checkpoint

11. Describe the location and general functions of axial muscles.
12. Describe the location and general functions of appendicular muscles.

See the blue Answers tab at the back of the book.

11-6 Axial muscles are muscles of the head and neck, vertebral column, trunk, and pelvic floor

Learning Outcome Identify the principal axial muscles of the body, plus their origins, insertions, actions, and innervation.

The axial muscles fall into logical groups based on location, function, or both. The groups do not always have distinct anatomical boundaries. For example, a function such as extension of the vertebral column involves muscles along its entire length and movement at each of the intervertebral joints. We discuss the axial muscles in four groups:

- *The Muscles of the Head and Neck.* This group includes muscles that move the face, tongue, and larynx. They are responsible for verbal and nonverbal communication—laughing, talking, frowning, smiling, whistling, and so on. These muscles are used while eating, especially in sucking and chewing; some also control eye movements to look at food. This group does not include muscles of the neck that are involved with movements of the vertebral column.
- *The Muscles of the Vertebral Column.* This group includes numerous flexors, extensors, and rotators of the vertebral column.

- *The Oblique and Rectus Muscles.* This group forms the muscular walls of the trunk between the first thoracic vertebra and the pelvis. In the thoracic area the ribs separate these muscles, but over the abdominal surface the muscles form broad muscular sheets. The neck also has oblique and rectus muscles. They do not form a complete muscular wall, but they share a common developmental origin with the oblique and rectus muscles of the trunk.
- *The Muscles of the Pelvic Floor.* These muscles extend between the sacrum and pelvic girdle. This group forms the *perineum* (per-ih-NĒ-um), a region anterior to the sacrum and coccyx between the inner thighs.

Muscles of the Head and Neck

We can divide the muscles of the head and neck into several functional groups. The *muscles of facial expression*, the *muscles of mastication* (chewing), the *muscles of the tongue*, and the *muscles of the pharynx* originate on the skull or hyoid bone.

Muscles involved with sight and hearing also are based on the skull. Here, we consider the *extrinsic eye muscles*—those associated with movements of the eye. In Chapter 17 we discuss the *intrinsic eye muscles*, which control the diameter of the pupil and the shape of the lens, and the tiny skeletal muscles associated with the auditory ossicles.

Among the *muscles of the anterior neck*, the extrinsic muscles of the larynx adjust the position of the hyoid bone and larynx. We examine the intrinsic laryngeal muscles, including those of the vocal cords, in Chapter 23.

Muscles of Facial Expression

The muscles of facial expression originate on the surface of the skull (**Figure 11-5**). At their insertions, the fibers of the epimysium are woven into those of the superficial fascia and the dermis of the skin. For this reason, when these muscles contract, the skin moves.

The largest group of facial muscles is associated with the mouth. The **orbicularis oris** constricts the opening, and other muscles move the lips or the corners of the mouth. The **buccinator** has two functions related to eating (in addition to its importance to musicians). During chewing, it cooperates with the masticatory muscles by moving food back across the teeth from the *vestibule*, the space inside the cheeks. In infants, the buccinator provides suction for suckling at the breast.

Smaller groups of muscles control movements of the eyebrows and eyelids, the scalp, the nose, and the external ear. The **epicranium** (ep-i-KRĀ-nĒ-um; *epi-*, on + *kranion*, skull), or scalp, contains the **temporoparietalis** and the **occipitofrontalis** (ok-sip-ih-tō-fron-TAL-is), which has a *frontal belly* and an *occipital belly*. The two bellies are separated by the **epicranial aponeurosis**, a thick, collagenous sheet.

The **platysma** (pla-TIZ-muh; *platys*, flat) covers the anterior surface of the neck. This muscle extends from the base of the neck to the periosteum of the mandible and the fascia at

Figure 11-5 Muscles of Facial Expression.

Given its name, what is the action of the levator anguli oris?

Table 11–2 Muscles of Facial Expression (Figure 11–5)

Region and Muscle	Origin	Insertion	Action	Innervation
MOUTH				
Buccinator	Alveolar process of maxilla and alveolar part of the mandible	Blends into fibers of orbicularis oris	Compresses cheeks	Facial nerve (VII)*
Depressor labii inferioris	Mandible between the anterior midline and the mental foramen	Skin of lower lip	Depresses lower lip	Facial nerve (VII)
Levator labii superioris	Inferior margin of orbit, superior to the infra-orbital foramen	Orbicularis oris	Elevates upper lip	Facial nerve (VII)
Levator anguli oris	Maxilla below the infra-orbital foramen	Corner of mouth	Elevates corner of mouth	Facial nerve (VII)
Mentalis	Incisive fossa of mandible	Skin of chin	Elevates and protrudes lower lip	Facial nerve (VII)
Orbicularis oris	Maxilla and mandible	Lips	Compresses, purses lips	Facial nerve (VII)
Risorius	Fascia surrounding parotid salivary gland	Angle of mouth	Draws corner of mouth to the side	Facial nerve (VII)
Depressor anguli oris	Anterolateral surface of mandibular body	Skin at angle of mouth	Depresses corner of mouth	Facial nerve (VII)
Zygomaticus major	Zygomatic bone near zygomaticomaxillary suture	Angle of mouth	Retracts and elevates corner of mouth	Facial nerve (VII)
Zygomaticus minor	Zygomatic bone posterior to zygomaticotemporal suture	Upper lip	Retracts and elevates upper lip	Facial nerve (VII)
EYE				
Corrugator supercilii	Orbital rim of frontal bone near nasal suture	Eyebrow	Pulls skin inferiorly and anteriorly; wrinkles brow	Facial nerve (VII)
Levator palpebrae superioris (Figure 11–6a,b)	Tendinous band around optic foramen	Upper eyelid	Elevates upper eyelid	Oculomotor nerve (III)**
Orbicularis oculi	Medial margin of orbit	Skin around eyelids	Closes eye	Facial nerve (VII)
NOSE				
Procerus	Nasal bones and lateral nasal cartilages	Aponeurosis at bridge of nose and skin of forehead	Moves nose, changes position and shape of nostrils	Facial nerve (VII)
Nasalis	Maxilla and nasal cartilages	Dorsum of nose	Compresses bridge, depresses tip of nose; elevates corners of nostrils	Facial nerve (VII)
EAR				
Temporoparietalis	Fascia around external ear	Epicranial aponeurosis	Tenses scalp, moves auricle of ear	Facial nerve (VII)
SCALP (EPICRANIUM)				
Occipitofrontalis				
Frontal belly	Epicranial aponeurosis	Skin of eyebrow and bridge of nose	Raises eyebrows, wrinkles forehead	Facial nerve (VII)
Occipital belly	Occipital bone and mastoid region of temporal bones	Epicranial aponeurosis	Tenses and retracts scalp	Facial nerve (VII)
NECK				
Platysma	Superior thorax between cartilage of 2nd rib and acromion of scapula	Mandible and skin of cheek	Tenses skin of neck; depresses mandible; pulls lower lip down	Facial nerve (VII)

*A Roman numeral refers to a cranial nerve.

**This muscle originates in association with the extrinsic eye muscles, so its innervation is unusual.

the corner of the mouth. One of the effects of aging is the loss of muscle tone in the platysma, resulting in a looseness of the skin of the anterior throat.

Now take another look at **Figure 11–5** with **Table 11–2**, which summarizes the muscles of facial expression by region. Focus on identifying the location and function of each of the major muscles named in this discussion.

Extrinsic Eye Muscles

Six **extrinsic eye muscles**, also known as the *oculomotor muscles*, originate on the surface of the orbit and control the position of each eye. These muscles, shown in **Figure 11–6**, are the **inferior rectus**, **medial rectus**, **superior rectus**, **lateral rectus**, **inferior oblique**, and **superior oblique**. Compare the illustrations in **Figure 11–6** with the details on these muscles in **Table 11–3**.

Figure 11–6 Extrinsic Eye Muscles.

Six muscles control eye movement. How many muscles are visible in a lateral view and how many muscles are visible in a medial view?

Table 11–3 Extrinsic Eye Muscles (Figure 11–6)

Muscle	Origin	Insertion	Action	Innervation
Inferior rectus	Sphenoid around optic canal	Inferior, medial surface of eyeball	Eye looks inferiorly	Oculomotor nerve (III)
Medial rectus	Sphenoid around optic canal	Medial surface of eyeball	Eye looks medially	Oculomotor nerve (III)
Superior rectus	Sphenoid around optic canal	Superior surface of eyeball	Eye looks superiorly	Oculomotor nerve (III)
Lateral rectus	Sphenoid around optic canal	Lateral surface of eyeball	Eye looks laterally	Abducens nerve (VI)
Inferior oblique	Maxilla at anterior portion of orbit	Inferior, lateral surface of eyeball	Eye rolls, looks superiorly and laterally	Oculomotor nerve (III)
Superior oblique	Sphenoid around optic canal	Superior, lateral surface of eyeball	Eye rolls, looks inferiorly and laterally	Trochlear nerve (IV)

Figure 11–7 Muscles of Mastication.

a Lateral view. The temporalis passes medial to the zygomatic arch to insert on the coronoid process of the mandible. The masseter inserts on the angle and lateral surface of the mandible.

b Lateral view, pterygoid muscles exposed. The location and orientation of the pterygoid muscles are seen after the overlying muscles and a portion of the mandible are removed.

Table 11–4 Muscles of Mastication (Figure 11–7)

Muscle	Origin	Insertion	Action	Innervation
Masseter	Zygomatic arch	Lateral surface of mandibular ramus	Elevates mandible and closes the jaws	Trigeminal nerve (V), mandibular division
Temporalis	Along temporal lines of skull	Coronoid process of mandible	Elevates mandible	Trigeminal nerve (V), mandibular division
Pterygoids (medial and lateral)	Lateral pterygoid plate	Medial surface of mandibular ramus	<i>Medial:</i> Elevates the mandible and closes the jaws or slides the mandible from side to side (lateral excursion) <i>Lateral:</i> Opens jaws, protrudes mandible, or performs lateral excursion	Trigeminal nerve (V), mandibular division Trigeminal nerve (V), mandibular division

Muscles of Mastication

The muscles of mastication move the mandible at the temporomandibular joint (TMJ) (Figure 11–7). The large **masseter** is the strongest jaw muscle. This muscle can be felt on the face below the zygomatic arch when a person chews. The **temporalis** muscle assists in elevating the mandible. The **pterygoid** (TER-ih-goyd) muscles, used in various combinations, can elevate, depress, or protract the mandible or slide it from side to side, a movement called *lateral excursion*. These movements are important in making efficient use of

teeth while chewing foods of various consistencies. Compare Figure 11–7 with the summary information on these muscles in Table 11–4.

Tips

The medial and lateral *pterygoid* muscles are named for their origin on the pterygoid (“winged”) portion of the sphenoid bone. The *pterodactyl* was a prehistoric winged reptile.

Figure 11–8 Muscles of the Tongue.

Muscles of the Tongue

The four muscles of the tongue have names ending in *glossus*, the Greek word for “tongue.” The **palatoglossus** originates at the palate, the **styloglossus** at the styloid process of the temporal bone, the **genioglossus** at the chin, and the **hyoglossus** (hī-ō-GLOS-us) at the hyoid bone (Figure 11–8). These muscles, used in various combinations, move the tongue in the subtle and complex patterns necessary for speech. They also maneuver food within the mouth in preparation for swallowing. Compare the illustrations of these muscles in Figure 11–8 with the summary in Table 11–5.

Muscles of the Pharynx

The muscles of the pharynx are responsible for initiating the swallowing process (Figure 11–9). The **pharyngeal** (fa-RIN-jē-al) **constrictor** muscles (*superior*, *middle*, and *inferior*)

Figure 11–9 Muscles of the Pharynx.

move food (in the form of a compacted mass called a *bolus*) into the esophagus by constricting the pharyngeal walls. The two **palatal** muscles—the *tensor veli palatini* and the *levator veli palatini*—elevate the soft palate and adjacent portions of the pharyngeal wall and also pull open the entrance to the auditory tube. The **laryngeal elevators** raise the larynx. As a result, swallowing repeatedly can help one adjust to pressure changes when flying or diving underwater by opening the entrance to the auditory tube. Used together, the illustrations in Figure 11–9 and the summary in Table 11–6 will give you a more complete understanding of these muscles.

Table 11–5 Muscles of the Tongue (Figure 11–8)

Muscle	Origin	Insertion	Action	Innervation
Genioglossus	Medial surface of mandible around chin	Body of tongue, hyoid bone	Depresses and protracts tongue	Hypoglossal nerve (XII)
Hyoglossus	Body and greater horn of hyoid bone	Side of tongue	Depresses and retracts tongue	Hypoglossal nerve (XII)
Palatoglossus	Anterior surface of soft palate	Side of tongue	Elevates tongue, depresses soft palate	Internal branch of accessory nerve (XI)
Styloglossus	Styloid process of temporal bone	Along the side to tip and base of tongue	Retracts tongue, elevates side of tongue	Hypoglossal nerve (XII)

Table 11–6 Muscles of the Pharynx (Figure 11–9)

Muscle	Origin	Insertion	Action	Innervation
PHARYNGEAL CONSTRICTORS				
Superior constrictor	Pterygoid process of sphenoid, medial surfaces of mandible	Median raphe attached to occipital bone	Constricts pharynx to propel bolus into esophagus	Branches of pharyngeal plexus (from CN X)
Middle constrictor	Horns of hyoid bone	Median raphe	Constricts pharynx to propel bolus into esophagus	Branches of pharyngeal plexus (from CN X)
Inferior constrictor	Cricoid and thyroid cartilages of larynx	Median raphe	Constricts pharynx to propel bolus into esophagus	Branches of pharyngeal plexus (from CN X)
PALATAL MUSCLES				
Levator veli palatine	Petrous part of temporal bone; tissues around the auditory tube	Soft palate	Elevates soft palate	Branches of pharyngeal plexus (from CN X)
Tensor veli palatine	Sphenoidal spine; tissues around the auditory tube	Soft palate	Elevates soft palate	Trigeminal nerve (V)
LARYNGEAL ELEVATORS*				
	Ranges from soft palate, to cartilage around inferior portion of auditory tube, to styloid process of temporal bone	Thyroid cartilage	Elevate larynx	Branches of pharyngeal plexus (from CN IX and CN X)

*Refers to the palatopharyngeus, salpingopharyngeus, and stylopharyngeus, assisted by the thyrohyoid, geniohyoid, stylohyoid, and hyoglossus, discussed in Tables 11–5 and 11–7.

Muscles of the Anterior Neck

The anterior muscles of the neck include (1) muscles that control the position of the larynx, (2) muscles that depress the mandible and tense the floor of the mouth, and (3) muscles that provide a stable foundation for muscles of the tongue and pharynx (**Figure 11–10**).

The **digastric** (dī-GAS-trik) is one of the main muscles that controls the position of the larynx. This muscle has two bellies, as the name implies (*di-*, two + *gaster*, stomach). The

anterior belly extends from the chin to the hyoid bone. The posterior belly continues from the hyoid bone to the mastoid portion of the temporal bone. Depending on which belly contracts and whether fixator muscles are stabilizing the position of the hyoid bone, the digastric can open the mouth by depressing the mandible, or it can elevate the larynx by raising the hyoid bone.

The digastric covers the broad, flat **mylohyoid**, which elevates the floor of the mouth or depresses the jaw when the hyoid bone is fixed. It is aided by the deeper **geniohyoid**

Clinical Note Intramuscular Injections

Drugs, including vaccines, are commonly injected into muscle tissues rather than directly into the bloodstream. (Accessing blood vessels is more complicated.) An **intramuscular (IM) injection** introduces a drug into the mass of a large skeletal muscle. Depending on the size of the muscle, up to 5 mL of fluid may be injected at one time. This drug then enters the circulation gradually. Uptake is generally faster and accompanied by less tissue irritation than when drugs are administered *intradermally* (injected into the dermis) or *subcutaneously* (injected into the subcutaneous layer). The injection technique and the injection site are based on the type of drug and its concentration.

For IM injections, the most common complications involve accidental injection into a blood vessel or nerve. The sudden entry of massive quantities of drug into the

bloodstream can have fatal consequences. Damage to a nerve can cause motor paralysis or sensory loss. For these reasons, the injection site must be selected with care. Bulky muscles that contain few large vessels or nerves are ideal sites. The gluteus medius or the posterior, lateral, superior part of the gluteus maximus is commonly selected. The deltoid of the arm, about 2.5 cm (1 in.) distal to the acromion, is another effective site. From a technical standpoint, the vastus lateralis of the thigh is a good site. Injections into this thick muscle will not encounter vessels or nerves but may cause pain later when the muscle is used in walking. This is the preferred injection site in infants before they start walking, as their gluteal and deltoid muscles are relatively small. This site is also used in people with atrophied gluteal and deltoid muscles.

(jē-nē-ō-HĪ-oyd) that extends between the hyoid bone and the chin. The **stylohyoid** forms a muscular connection between the hyoid bone and the styloid process of the skull.

The **sternocleidomastoid** (ster-nō-klī-dō-MAS-toyd) extends from the clavicle and the sternum to the mastoid region of the skull and turns the head obliquely to the opposite side (**Figure 11-10**). The **omohyoid** attaches to the scapula, the clavicle and first rib, and the hyoid bone. The other members of this group are strap-like muscles that extend between the sternum and larynx (*sternothyroid*) or hyoid bone (*sternohyoid*), and between the larynx and hyoid bone (*thyrohyoid*).

Review the muscles discussed here and shown in

Figure 11-10 with the summary details in **Table 11-7**.

Muscles of the Vertebral Column

The muscles of the vertebral column are covered by more superficial back muscles, such as the trapezius and latissimus dorsi (**Figure 11-4b**). The main muscles of this group are the **erector spinae** (SPĪ-nē) muscles, which include superficial and deep layers. The superficial layer can be divided into **spinalis**, **longissimus** (lon-JIS-ih-mus), and **iliocostalis** (ē-lē-ō-kos-TAL-is) groups (**Figure 11-11**). In the inferior lumbar and sacral regions, the boundary between the longissimus and iliocostalis is indistinct. When contracting together, the erector spinae extend the vertebral column. When the muscles on only one side contract, the result is lateral flexion of the vertebral column.

Figure 11-10 Muscles of the Anterior Neck.

Which muscles insert on the hyoid bone?

Table 11-7 Muscles of the Anterior Neck (Figure 11-10)

Muscle	Origin	Insertion	Action	Innervation
Digastric	Two bellies: <i>anterior</i> from inferior surface of mandible at chin; <i>posterior</i> from mastoid region of temporal bone	Hyoid bone	Depresses mandible or elevates larynx	<i>Anterior belly:</i> Trigeminal nerve (V), mandibular division <i>Posterior belly:</i> Facial nerve (VII)
Geniohyoid	Medial surface of mandible at chin	Hyoid bone	Depresses mandible or elevates larynx and pulls hyoid bone anteriorly	Cervical nerve C ₁ by hypoglossal nerve (XII)
Mylohyoid	Mylohyoid line of mandible	Median connective tissue band (raphe) that runs to hyoid bone	Elevates floor of mouth and hyoid bone or depresses mandible	Trigeminal nerve (V), mandibular division
Omohyoid (superior and inferior bellies united at central tendon anchored to clavicle and first rib)	Superior border of scapula near scapular notch	Hyoid bone	Depresses hyoid bone and larynx	Cervical spinal nerves C ₂ –C ₃
Sternohyoid	Clavicle and manubrium	Hyoid bone	Depresses hyoid bone and larynx	Cervical spinal nerves C ₁ –C ₃
Sternothyroid	Dorsal surface of manubrium and first costal cartilage	Thyroid cartilage of larynx	Depresses hyoid bone and larynx	Cervical spinal nerves C ₁ –C ₃
Stylohyoid	Styloid process of temporal bone	Hyoid bone	Elevates larynx	Facial nerve (VII)
Thyrohyoid	Thyroid cartilage of larynx	Hyoid bone	Elevates thyroid, depresses hyoid bone	Cervical spinal nerves C ₁ –C ₂ by hypoglossal nerve (XII)
Sternocleidomastoid	Two bellies: <i>clavicular head</i> attaches to sternal end of clavicle; <i>sternal head</i> attaches to manubrium	Mastoid region of skull and lateral portion of superior nuchal line	Together, they flex the neck; alone, one side flexes head toward shoulder and rotates face to opposite side	Accessory nerve (XI) and cervical spinal nerves (C ₂ –C ₃) of cervical plexus

Deep to the spinalis muscles, smaller muscles interconnect and stabilize the vertebrae. These muscles include the **semispinalis** group; the **multifidus** (mul-TIF-ih-dus); and the **interspinales**, **intertransversarii** (in-ter-tranz-ver-SAR-ē-ī), and **rotatores** (rō-teh-TOR-ē-z) (Figure 11-11). In various combinations, they produce slight extension or rotation of the vertebral column. They are also important in making delicate adjustments in the positions of individual vertebrae, and they stabilize adjacent vertebrae. If injured, these muscles can start a cycle of pain → muscle stimulation → contraction → pain. Resultant pressure on adjacent spinal nerves can lead to sensory losses and mobility limitations. Many of the warm-up and stretching exercises recommended before athletic activity are intended to prepare these small but very important muscles for their supporting role.

The muscles of the vertebral column include many posterior extensors, but few anterior flexors. Why doesn't the vertebral column have massive **flexor** muscles? One reason is that many of the large trunk muscles flex the vertebral column when they contract. A second reason is that most of the body weight lies anterior to the vertebral column, so gravity tends to flex the spine. However, a few spinal flexors are associated with the anterior surface of the vertebral column. In the neck, the **longus capitis** (KAP-ih-tus) and the **longus colli** rotate or flex the neck, depending on whether the muscles of one or both sides are contracting (Figure 11-11). In the lumbar region, the

large **quadratus** (kwad-RĀ-tus) **lumborum** flexes the vertebral column and depresses the ribs.

Use the illustrations in Figure 11-11 along with the details in Table 11-8 to further your understanding.

+ Clinical Note Signs of Stroke

A stroke, or *cerebrovascular accident*, may manifest in the muscular system. This happens, for example, when a clot in a blood vessel interrupts blood flow to the brain, and a muscle does not receive the signal to contract. Early recognition and treatment of a stroke can make all the difference in the outcome of this threatening disorder. Public service announcements by the National Stroke Association alert the public about stroke by means of a catchy phrase—“Act FAST”:

- **F** stands for **Face**: Ask the person to smile and look for a droop in the facial muscles on the affected side.
- **A** stands for **Arm**: Ask the person to raise both arms and determine whether they have the strength to do this.
- **S** stands for **Speech**: Ask the person to repeat a few words and listen for slurred speech to determine if pharyngeal and laryngeal muscles are affected.
- **T** stands for **Time**: If you observe any of these signs, it's time to call 9-1-1 for help.

Figure 11–11 Muscles of the Vertebral Column.

Table 11–8 Muscles of the Vertebral Column (Figure 11–11)

Group and Muscles		Origin	Insertion	Action	Innervation
SUPERFICIAL LAYER					
Splenius (splenius capitis, splenius cervicis)		Spinous processes and ligaments connecting inferior cervical and superior thoracic vertebrae	Mastoid process, occipital bone of skull, and superior cervical vertebrae	Together, the two sides extend neck; alone, each rotates and laterally flexes neck to that side	Cervical spinal nerves
Erector spinae					
Spinalis group	Spinalis cervicis	Inferior portion of ligamentum nuchae and spinous process of C ₇	Spinous process of axis	Extends neck	Cervical spinal nerves
	Spinalis thoracis	Spinous processes of inferior thoracic and superior lumbar vertebrae	Spinous processes of superior thoracic vertebrae	Extends vertebral column	Thoracic and lumbar spinal nerves
Longissimus group	Longissimus capitis	Transverse processes of inferior cervical and superior thoracic vertebrae	Mastoid process of temporal bone	Together, the two sides extend head; alone, each rotates and laterally flexes neck to that side	Cervical and thoracic spinal nerves
	Longissimus cervicis	Transverse processes of superior thoracic vertebrae	Transverse processes of middle and superior cervical vertebrae	Together, the two sides extend head; alone, each rotates and laterally flexes neck to that side	Cervical and thoracic spinal nerves
	Longissimus thoracis	Broad aponeurosis and transverse processes of inferior thoracic and superior lumbar vertebrae; joins iliocostalis	Transverse processes of superior vertebrae and inferior surfaces of ribs	Together, the two sides extend vertebral column; alone, each produces lateral flexion to that side	Thoracic and lumbar spinal nerves
Iliocostalis group	Iliocostalis cervicis	Superior borders of vertebrosteral ribs near the angles	Transverse processes of middle and inferior cervical vertebrae	Extends or laterally flexes neck, elevates ribs	Cervical and superior thoracic spinal nerves
	Iliocostalis thoracis	Superior borders of inferior seven ribs medial to the angles	Upper ribs and transverse process of last cervical vertebra	Stabilizes thoracic vertebrae in extension	Thoracic spinal nerves
	Iliocostalis lumborum	Iliac crest, sacral crests, and spinous processes	Inferior surfaces of inferior seven ribs near their angles	Extends vertebral column, depresses ribs	Inferior thoracic and lumbar spinal nerves
DEEP LAYER					
Semispinalis group	Semispinalis capitis	Articular processes of inferior cervical and transverse processes of superior thoracic vertebrae	Occipital bone, between nuchal lines	Together, the two sides extend head; alone, each extends and laterally flexes neck	Cervical spinal nerves
	Semispinalis cervicis	Transverse processes of T ₁ –T ₅ or T ₆	Spinous processes of C ₂ –C ₅	Extends vertebral column and rotates toward opposite side	Cervical spinal nerves
	Semispinalis thoracis	Transverse processes of T ₆ –T ₁₀	Spinous processes of C ₅ –T ₄	Extends vertebral column and rotates toward opposite side	Thoracic spinal nerves
	Multifidus	Sacrum and transverse processes of each vertebra	Spinous processes of the third or fourth more superior vertebrae	Extends vertebral column and rotates toward opposite side	Cervical, thoracic, and lumbar spinal nerves
	Rotatores	Transverse processes of each vertebra	Spinous processes of adjacent, more superior vertebra	Extends vertebral column and rotates toward opposite side	Cervical, thoracic, and lumbar spinal nerves
	Interspinales	Spinous processes of each vertebra	Spinous processes of more superior vertebra	Extends vertebral column	Cervical, thoracic, and lumbar spinal nerves
	Intertransversarii	Transverse processes of each vertebra	Transverse process of more superior vertebra	Laterally flexes the vertebral column	Cervical, thoracic, and lumbar spinal nerves
SPINAL FLEXORS					
Longus capitis		Transverse processes of cervical vertebrae	Base of the occipital bone	Together, the two sides flex the neck; alone, each rotates head to that side	Cervical spinal nerves
Longus colli		Anterior surfaces of cervical and superior thoracic vertebrae	Transverse processes of superior cervical vertebrae	Flexes or rotates neck; limits hyperextension	Cervical spinal nerves
Quadratus lumborum		Iliac crest and iliolumbar ligament	Last rib and transverse processes of lumbar vertebrae	Together, they depress ribs; alone, each side laterally flexes vertebral column	Thoracic and lumbar spinal nerves

Oblique and Rectus Muscles and the Diaphragm

The oblique and rectus muscle groups of the anterior body wall share developmental origins. We include the diaphragm here because it develops in association with the other muscles of the chest wall.

Oblique and Rectus Muscles

The oblique and rectus muscle groups lie within the body wall, between the spinous processes of vertebrae and the ventral midline. (You may want to look back at **Figure 11-4a** for an overview, and then take another look at **Figure 11-12**.) The oblique muscles compress underlying structures or rotate the

Figure 11-12 Oblique and Rectus Muscles and the Diaphragm.

vertebral column, depending on whether one or both sides contract. The rectus muscles are important flexors of the vertebral column, acting in opposition to the erector spinae. We can subdivide each of these groups into cervical, thoracic, and abdominal regions (Table 11–9).

The oblique group includes the **scalene** muscles of the neck (Figure 11–12a) and the **intercostal** and **transversus** muscles of the thorax (Figure 11–12b,c). The scalene muscles (*anterior*, *middle*, and *posterior*) elevate the first two ribs and assist in flexion of the neck. In the thorax, the oblique muscles extend between the ribs, with the **external intercostal muscles** covering the **internal intercostal muscles**. Both groups of intercostal muscles aid in breathing movements of the ribs.

A small **transversus thoracis** (THOR-ah-sis) crosses the posterior surface of the sternum and is separated from the pleural cavity by the parietal pleura, a *serous membrane*. The sternum occupies the place where we might otherwise expect thoracic rectus muscles to be.

The same basic pattern of musculature extends unbroken across the abdominopelvic surface (Figure 11–12b,d). Here, the muscles are the **external oblique**, **internal oblique**, **transversus abdominis**, and **rectus abdominis** (commonly called the “abs”). The rectus abdominis inserts at the xiphoid process and originates near the pubic symphysis. This muscle is longitudinally divided by the **linea alba** (white line), a median collagenous partition (Figure 11–12b).

Table 11–9 Oblique and Rectus Muscle Groups (Figure 11–12)

Group and Muscles	Origin	Insertion	Action	Innervation*
OBLIQUE GROUP				
<i>Cervical region</i>				
Scalenes (anterior, middle, and posterior)	Transverse and costal processes of cervical vertebrae	Superior surfaces of first two ribs	Elevate ribs or flex neck	Cervical nerves
<i>Thoracic region</i>				
External intercostals	Inferior border of each rib	Superior border of more inferior rib	Elevate ribs	Intercostal nerves (branches of thoracic nerves)
Internal intercostals	Superior border of each rib	Inferior border of the preceding rib	Depress ribs	Intercostal nerves (branches of thoracic nerves)
Transversus thoracis	Posterior surface of sternum	Cartilages of ribs	Depresses ribs	Intercostal nerves (branches of thoracic nerves)
Serratus posterior superior (Figure 11–14b)	Spinous processes of C ₇ –T ₃ and ligamentum nuchae	Superior borders of ribs 2–5 near angles	Elevates ribs, enlarges thoracic cavity	Thoracic nerves (T ₁ –T ₄)
Serratus posterior inferior (Figure 11–14b)	Aponeurosis from spinous processes of T ₁₀ –L ₃	Inferior borders of ribs 8–12	Pulls ribs inferiorly; also pulls outward, opposing diaphragm	Thoracic nerves (T ₉ –T ₁₂)
<i>Abdominal region</i>				
External oblique	External and inferior borders of ribs 5–12	Linea alba and iliac crest	Compresses abdomen, depresses ribs, flexes or bends spine	Intercostal, iliohypogastric, and ilioinguinal nerves
Internal oblique	Thoracolumbar fascia and iliac crest	Inferior ribs, xiphoid process, and linea alba	Compresses abdomen, depresses ribs, flexes or bends spine	Intercostal, iliohypogastric, and ilioinguinal nerves
Transversus abdominis	Cartilages of ribs 6–12, iliac crest, and thoracolumbar fascia	Linea alba and pubis	Compresses abdomen	Intercostal, iliohypogastric, and ilioinguinal nerves
RECTUS GROUP				
<i>Cervical region</i>				
<i>Thoracic region</i>				
Diaphragm	Xiphoid process, cartilages of ribs 4–10, and anterior surfaces of lumbar vertebrae	Central tendinous sheet	Contraction expands thoracic cavity and compresses abdominopelvic cavity	Phrenic nerve (C ₃ –C ₅)
<i>Abdominal region</i>				
Rectus abdominis	Superior surface of pubis around symphysis	Inferior surfaces of costal cartilages (ribs 5–7) and xiphoid process	Depresses ribs, flexes vertebral column, compresses abdomen	Intercostal nerves (T ₇ –T ₁₂)

*Where appropriate, spinal nerves involved are given in parentheses.

Figure 11–13 Muscles of the Pelvic Floor.

The rectus abdominis is separated into segments by transverse bands of collagen fibers called **tendinous inscriptions**. Each segment contains muscle fibers that extend longitudinally, originating and inserting on the tendinous inscriptions. The bulging of enlarged muscle fibers of the rectus abdominis between these tendinous inscriptions produces what we call a “six-pack.”

The Diaphragm

The term *diaphragm* refers to any muscular sheet that forms a wall. When used without a modifier, however, **diaphragm** specifies the muscular partition that separates the abdominopelvic and thoracic cavities (**Figure 11-12c**). The diaphragm is a major muscle used in breathing and is further discussed in Chapter 23.

Now that you have been introduced to **Figure 11-12**, refer to it along with the summary details presented in **Table 11-9**.

Muscles of the Pelvic Floor

The muscles of the pelvic floor extend from the sacrum and coccyx to the ischium and pubis (**Figure 11-13**). These muscles (1) support the organs of the pelvic cavity, (2) flex the sacrum and coccyx, and (3) control the movement of materials through the urethra and anus. They are summarized in **Table 11-10**.

The boundaries of the **perineum** are formed by the inferior margins of the pelvis. A line drawn between the ischial tuberosities divides the perineum into two triangles: an anterior **urogenital triangle** and a posterior **anal triangle** (**Figure 11-13**). The superficial muscles of the urogenital

Table 11-10 Muscles of the Pelvic Floor (Figure 11-13)

Group and Muscle		Origin	Insertion	Action	Innervation*
UROGENITAL TRIANGLE					
Superficial muscles	Bulbospongiosus Males	Collagen sheath at base of penis; fibers cross over urethra	Median raphe and central tendon of perineum	Compresses base and stiffens penis; ejects urine or semen	Pudendal nerve, perineal branch (S ₂ –S ₄)
	Females	Collagen sheath at base of clitoris; fibers run on either side of urethral and vaginal opening	Central tendon of perineum	Compresses and stiffens clitoris; narrows vaginal opening	Pudendal nerve, perineal branch (S ₂ –S ₄)
	Ischiocavernosus	Ischial ramus and tuberosity	Pubic symphysis anterior to base of penis or clitoris	Compresses and stiffens penis or clitoris	Pudendal nerve, perineal branch (S ₂ –S ₄)
	Superficial transverse perineal muscle	Ischial ramus	Central tendon of perineum	Stabilizes central tendon of perineum	Pudendal nerve, perineal branch (S ₂ –S ₄)
Deep muscles	Deep transverse perineal muscle	Ischial ramus	Central tendon of perineum	Stabilizes central tendon of perineum	Pudendal nerve, perineal branch (S ₂ –S ₄)
	External urethral sphincter				
	Males	Ischial and pubic rami	To median raphe at base of penis; inner fibers encircle urethra	Closes urethra; compresses prostate and bulbourethral glands	Pudendal nerve, perineal branch (S ₂ –S ₄)
	Females	Ischial and pubic rami	To median raphe; inner fibers encircle urethra	Closes urethra; compresses vagina and greater vestibular glands	Pudendal nerve, perineal branch (S ₂ –S ₄)
ANAL TRIANGLE					
Pelvic diaphragm Coccygeus		Ischial spine	Lateral, inferior borders of sacrum and coccyx	Flexes coccygeal joints; tenses and supports pelvic floor	Inferior sacral nerves (S ₄ –S ₅)
Levator ani Iliococcygeus		Ischial spine, pubis	Coccyx and median raphe	Tenses floor of pelvis; flexes coccygeal joints; elevates and retracts anus	Pudendal nerve (S ₂ –S ₄)
Pubococcygeus		Inner margins of pubis	Coccyx and median raphe	Tenses floor of pelvis; flexes coccygeal joints; elevates and retracts anus	Pudendal nerve (S ₂ –S ₄)
External anal sphincter		By tendon from coccyx	Encircles anal opening	Closes anal opening	Pudendal nerve, hemorrhoidal branch (S ₂ –S ₄)

*Where appropriate, spinal nerves involved are given in parentheses.

triangle are the muscles of the external genitalia. They cover deeper muscles that strengthen the pelvic floor and encircle the urethra. An even more extensive muscular sheet, the **pelvic diaphragm**, forms the muscular foundation of the anal triangle. This layer extends as far as the pubic symphysis.

The urogenital and pelvic diaphragms do not completely close the pelvic outlet. The urethra and anus (in males and females), as well as the vagina in females, pass through them to open on the exterior. Muscular sphincters surround the passageways, and the external sphincters permit voluntary control of urination and defecation. Muscles, nerves, and blood vessels also pass through the pelvic outlet as they travel to or from the lower limbs.

As a learning aid, once again, refer to the illustrations in **Figure 11–13** with the specific details in **Table 11–10**.

See the blue Answers tab at the back of the book.

11-7 Appendicular muscles are muscles of the shoulders, upper limbs, pelvis, and lower limbs

Learning Outcome Identify the principal appendicular muscles of the body, plus their origins, insertions, actions, and innervation, and compare the major functional differences between the upper and lower limbs.

The appendicular musculature positions and stabilizes the pectoral and pelvic girdles and moves the upper and lower limbs. There are two major groups of appendicular muscles: (1) *the muscles of the shoulders (pectoral girdles) and upper limbs* and (2) *the muscles of the pelvis (pelvic girdle) and lower limbs*.

The functions and required ranges of motion are very different between these groups. The muscular connections between the pectoral girdles and the axial skeleton increase the mobility of the arms and act as shock absorbers. For example, while jogging, a person can still perform delicate hand movements, because the muscular connections between the axial and appendicular components of the skeleton smooth out the bounces in their stride. In contrast, the pelvic girdle has evolved to transfer weight from the axial to the appendicular skeleton. Rigid, bony articulations are essential, because the emphasis is on strength rather than versatility, and a muscular connection would reduce the efficiency of the transfer.

Figure 11–14 and **Table 11–11** introduce the organization and actions of the appendicular muscles of the trunk.

Table 11–11 Muscles That Position the Pectoral Girdle (Figures 11–14 and 11–15)

Muscle	Origin	Insertion	Action	Innervation*
Levator scapulae	Transverse processes of first four cervical vertebrae	Vertebral border of scapula near superior angle	Elevates scapula	Cervical nerves C ₃ –C ₄ and dorsal scapular nerve (C ₅)
Pectoralis minor	Anterior–superior surfaces of ribs 2–4, 2–5, or 3–5 depending on anatomical variation	Coracoid process of scapula	Depresses and protracts shoulder; rotates scapula so glenoid cavity moves inferiorly (downward rotation); elevates ribs if scapula is stationary	Medial pectoral nerve (C ₈ , T ₁)
Rhomboid major	Spinous processes of superior thoracic vertebrae	Vertebral border of scapula from spine to inferior angle	Adducts scapula and performs downward rotation	Dorsal scapular nerve (C ₅)
Rhomboid minor	Spinous processes of vertebrae C ₇ –T ₁	Vertebral border of scapula near spine	Adducts scapula and performs downward rotation	Dorsal scapular nerve (C ₅)
Serratus anterior	Anterior and superior margins of ribs 1–8 or 1–9	Anterior surface of vertebral border of scapula	Protracts shoulder; rotates scapula so glenoid cavity moves superiorly (upward rotation)	Long thoracic nerve (C ₅ –C ₇)
Subclavius	First rib	Clavicle (inferior border)	Depresses and protracts shoulder	Nerve to subclavius (C ₅ –C ₆)
Trapezius	Occipital bone, ligamentum nuchae, and spinous processes of thoracic vertebrae	Clavicle and scapula (acromion and scapular spine)	Depends on active region and state of other muscles; may (1) elevate, retract, depress, or rotate scapula upward, (2) elevate clavicle, or (3) extend neck	Accessory nerve (XI) and cervical nerves (C ₃ –C ₄)

*Where appropriate, spinal nerves involved are given in parentheses.

Media resource available for this topic: A&P Flix: Origins, Insertions, Actions, Innervations: Rectus Abdominis

Figure 11–14 An Overview of the Appendicular Muscles of the Trunk.

Muscles of the Shoulders and Upper Limbs

We can divide the muscles associated with the shoulders and upper limbs into four groups: (1) *muscles that position the pectoral girdle*, (2) *muscles that move the arm*, (3) *muscles that move the forearm and hand*, and (4) *muscles that move the fingers*.

Muscles That Position the Pectoral Girdle

The large, superficial **trapezius**, commonly called the “traps,” cover the back and portions of the neck, reaching to the base of the skull. This muscle originates along the midline of the neck and back and inserts on the clavicles and the scapular spines (**Figure 11–15**). The trapezius is innervated by more than one

nerve. For this reason, specific regions can be made to contract independently, and their actions are quite varied.

On the chest, the **serratus** (seh-RĀ-tus) **anterior** originates along the anterior surfaces of several ribs (**Figure 11–15a,b**). This fan-shaped muscle inserts along the anterior margin of the vertebral border of the scapula. When the serratus anterior contracts, it abducts (protracts) the scapula and swings the shoulder anteriorly.

Two other deep chest muscles arise along the anterior surfaces of the ribs on either side. The **subclavius** (sub-KLĀ-vē-us; *sub-*, below + *clavius*, clavicle) inserts on the inferior border of the clavicle (**Figure 11–15a**). When it contracts, it depresses and protracts the scapular end of the clavicle. Because ligaments connect this end to the shoulder joint and scapula, those

Figure 11–14 An Overview of the Appendicular Muscles of the Trunk. (*continued*)

structures move as well. The **pectoralis** (pek-tō-RA-lis) **minor** attaches to the coracoid process of the scapula. The contraction of this muscle generally acts as a synergist to the subclavius.

Removing the trapezius reveals the **rhomboid major**, **rhomboid minor**, and **levator scapulae** (Figure 11–15b). These muscles are attached to the posterior surfaces of the cervical and thoracic vertebrae. They insert along the vertebral border of each scapula, between the superior and inferior angles. Contraction of a rhomboid adducts (retracts) the scapula on that side. The levator scapulae, as its name implies, elevates the scapula.

Now take a look at how Figure 11–15 compares with the summary in Table 11–11.

Muscles That Move the Arm

Muscles that move the arm have their actions at the shoulder joint (Figure 11–16 and Table 11–12). The **deltoid** is the major abductor, but the **supraspinatus** (sū-pra-spī-NĀ-tus) acts as a synergist at the start of this movement. The **subscapularis** and **teres major** produce medial rotation at the shoulder, whereas the **infraspinatus** and the **teres minor** produce lateral rotation. All these muscles originate on the scapula. The small **coracobrachialis** (KOR-uh-kō-brā-kē-AH-lis) is the only muscle attached to the scapula that produces flexion and adduction at the shoulder (Figure 11–16a).

Table 11–12 Muscles That Move the Arm (Figures 11–14 to 11–16)

Muscle	Origin	Insertion	Action	Innervation*
Deltoid	Clavicle and scapula (acromion and adjacent scapular spine)	Deltoid tuberosity of humerus	<i>Whole muscle:</i> abduction at shoulder; <i>anterior part:</i> flexion and medial rotation; <i>posterior part:</i> extension and lateral rotation	Axillary nerve (C ₅ –C ₆)
Supraspinatus	Supraspinous fossa of scapula	Greater tubercle of humerus	Abduction at shoulder	Suprascapular nerve (C ₅)
Subscapularis	Subscapular fossa of scapula	Lesser tubercle of humerus	Medial rotation at shoulder	Subscapular nerves (C ₅ –C ₆)
Teres major	Inferior angle of scapula	Passes medially to reach the medial lip of intertubercular sulcus of humerus	Extension, adduction, and medial rotation at shoulder	Lower subscapular nerve (C ₅ –C ₆)
Infraspinatus	Infraspinous fossa of scapula	Greater tubercle of humerus	Lateral rotation at shoulder	Suprascapular nerve (C ₅ –C ₆)
Teres minor	Lateral border of scapula	Passes laterally to reach the greater tubercle of humerus	Lateral rotation at shoulder	Axillary nerve (C ₅)
Coracobrachialis	Coracoid process	Medial margin of shaft of humerus	Adduction and flexion at shoulder	Musculocutaneous nerve (C ₅ –C ₇)
Pectoralis major	Cartilages of ribs 2–6, body of sternum, and inferior, medial portion of clavicle	Crest of greater tubercle and lateral lip of intertubercular sulcus of humerus	Flexion, adduction, and medial rotation at shoulder	Pectoral nerves (C ₅ –T ₁)
Latissimus dorsi	Spinous processes of inferior thoracic and all lumbar vertebrae, ribs 8–12, and thoracolumbar fascia	Floor of intertubercular sulcus of the humerus	Extension, adduction, and medial rotation at shoulder	Thoracodorsal nerve (C ₆ –C ₈)
Triceps brachii (long head)	See Table 11–13			

*Where appropriate, spinal nerves involved are given in parentheses.

Tips

The supraspinatus and infraspinatus are named for their origins above and below the spine of the scapula, respectively, not because they are located on the spinal column.

The **pectoralis major** extends between the anterior portion of the chest and the crest of the greater tubercle of the humerus (**Figure 11–16a**). The **latissimus dorsi** (la-TIS-i-mus DOR-sē) extends between the thoracic vertebrae at the posterior midline and the intertubercular sulcus of the humerus (**Figure 11–16b**). The pectoralis major produces flexion at the shoulder joint, and the latissimus dorsi produces extension. These muscles, commonly known as the “pecs” and the “lats,” can also work together to produce adduction and medial rotation of the humerus at the shoulder.

Collectively, the supraspinatus, infraspinatus, teres minor, and subscapularis and their associated tendons form the **rotator cuff**. Sports that involve throwing a ball, such as baseball or football, place considerable strain on the rotator cuff, and rotator cuff injuries are common.

Tips

The acronym SITS is useful in remembering the four muscles of the rotator cuff.

See how the illustrations in **Figure 11–16** relate to the summary information in **Table 11–12**.

Muscles That Move the Forearm and Hand

The forearm is the region of the upper limb between the elbow and the hand, and the hand is the region distal to the radiocarpal joint, comprising the wrist, palm, and fingers. The muscles of this region can be grouped according to their actions at the elbow and hand, and include flexors, extensors, pronators, and supinators.

Action at the Elbow. Most of the muscles that move the forearm and hand originate on the humerus and insert on the forearm and wrist. There are two exceptions: the biceps brachii and triceps brachii. The **biceps brachii** and the *long head* of the **triceps brachii** originate on the scapula and insert on the bones of the forearm (**Figure 11–17**).

Figure 11–16 Muscles That Move the Arm.

Figure 11–17 Muscles That Move the Forearm and Hand.

Where are the origins of the heads of the triceps brachii.

Media resource available for this topic: A&P Flix: Group Muscle Actions and Joints: Muscles of the Elbow Joint

Table 11–13 Muscles That Move the Forearm and Hand (Figures 11–17 and 11–18e)

Muscle	Origin	Insertion	Action	Innervation*	
ACTION AT THE ELBOW					
Flexors	Biceps brachii	Short head from the coracoid process; long head from the supraglenoid tubercle (both on the scapula)	Tuberosity of radius	Flexes and supinates forearm at elbow; flexes arm at shoulder	Musculocutaneous nerve (C ₅ –C ₆)
	Brachialis	Anterior, distal surface of humerus	Tuberosity of ulna	Flexes forearm at elbow	Musculocutaneous nerve (C ₅ –C ₆) and radial nerve (C ₇ –C ₈)
	Brachioradialis	Ridge superior to the lateral epicondyle of humerus	Lateral aspect of styloid process of radius	Flexes forearm at elbow	Radial nerve (C ₅ –C ₆)
Extensors	Anconeus	Posterior, inferior surface of lateral epicondyle of humerus	Lateral margin of olecranon on ulna	Extension at elbow	Radial nerve (C ₇ –C ₈)
	Triceps brachii				
	Lateral head	Superior, lateral margin of humerus	Olecranon of ulna	Extends forearm at elbow	Radial nerve (C ₆ –C ₈)
	Long head	Infraglenoid tubercle of scapula	Olecranon of ulna	Extends forearm at elbow; extension and adduction at the shoulder	Radial nerve (C ₆ –C ₈)
	Medial head	Posterior surface of humerus inferior to radial groove	Olecranon of ulna	Extends forearm at elbow	Radial nerve (C ₆ –C ₈)
PRONATORS/SUPINATORS					
	Pronator quadratus	Anterior and medial surfaces of distal portion of ulna	Anterolateral surface of distal portion of radius	Pronation	Median nerve (C ₈ –T ₁)
	Pronator teres	Medial epicondyle of humerus and coronoid process of ulna	Midlateral surface of radius	Pronation	Median nerve (C ₆ –C ₇)
	Supinator	Lateral epicondyle of humerus, annular ligament, and ridge near radial notch of ulna	Anterolateral surface of radius distal to the radial tuberosity	Supination	Deep radial nerve (C ₆ –C ₈)
ACTION AT THE WRIST					
Flexors	Flexor carpi radialis	Medial epicondyle of humerus	Bases of second and third metacarpal bones	Flexes and abducts hand at the wrist	Median nerve (C ₆ –C ₇)
	Flexor carpi ulnaris	Medial epicondyle of humerus; adjacent medial surface of olecranon and anteromedial portion of ulna	Pisiform, hamate, and base of fifth metacarpal bone	Flexes and adducts hand at the wrist	Ulnar nerve (C ₈ –T ₁)
	Palmaris longus	Medial epicondyle of humerus	Palmar aponeurosis and flexor retinaculum	Flexes hand; tenses skin and aponeurosis of palm	Median nerve (C ₆ –C ₇)
Extensors	Extensor carpi radialis longus	Lateral supracondylar ridge of humerus	Base of second metacarpal bone	Extends and abducts hand at the wrist	Radial nerve (C ₆ –C ₇)
	Extensor carpi radialis brevis	Lateral epicondyle of humerus	Base of third metacarpal bone	Extends and abducts hand at the wrist	Radial nerve (C ₆ –C ₇)
	Extensor carpi ulnaris	Lateral epicondyle of humerus; adjacent dorsal surface of ulna	Base of fifth metacarpal bone	Extends and adducts hand at the wrist	Deep radial nerve (C ₆ –C ₈)

*Where appropriate, spinal nerves involved are given in parentheses.

The triceps brachii inserts on the olecranon of the ulna. Contraction of the triceps brachii extends the elbow, as when doing push-ups. The biceps brachii inserts on the radial tuberosity, a roughened bump on the anterior surface of the radius. Contraction of the biceps brachii flexes the elbow and supinates the forearm. With the forearm pronated (palm facing posteriorly), the biceps brachii cannot function effectively. As a result, a person is strongest when the elbow is flexed with a supinated forearm. The biceps brachii then makes a prominent bulge.

The biceps brachii is important in stabilizing the shoulder joint. The short head originates on the coracoid process and supports the posterior surface of the joint capsule. The long head originates at the supraglenoid tubercle, inside the shoulder joint. After crossing the head of the humerus, it passes along the intertubercular sulcus. In this position, the tendon helps to hold the head of the humerus within the glenoid cavity while arm movements are under way.

More muscles than these are shown in **Figure 11–17** and summarized in **Table 11–13**. When studying these muscles,

Figure 11–18 Muscles That Move the Hand and Fingers.**c** Posterior view, middle layer**d** Posterior view, deepest layer**e** Supination and pronation

Table 11-14 Muscles That Move the Hand and Fingers (Figure 11-18)

Muscle	Origin	Insertion	Action	Innervation*
Abductor pollicis longus	Proximal dorsal surfaces of ulna and radius	Lateral margin of first metacarpal bone	Abducts and extends thumb	Deep radial nerve (C ₆ –C ₇)
Extensor digitorum	Lateral epicondyle of humerus	Posterior surfaces of the phalanges, digits 2–5	Extends fingers 2-5 and hand	Deep radial nerve (C ₆ –C ₈)
Extensor pollicis brevis	Shaft of radius distal to origin of abductor pollicis longus	Base of proximal phalanx of thumb	Extends thumb	Deep radial nerve (C ₆ –C ₇)
Extensor pollicis longus	Posterior and lateral surfaces of ulna and interosseous membrane	Base of distal phalanx of thumb	Extends thumb	Deep radial nerve (C ₆ –C ₈)
Extensor indicis	Posterior surface of ulna and interosseous membrane	Posterior surface of phalanges of index finger (digit 2), with tendon of extensor digitorum	Extends index finger (digit 2)	Deep radial nerve (C ₆ –C ₈)
Extensor digiti minimi	By extensor tendon to lateral epicondyle of humerus and from intermuscular septa	Posterior surface of proximal phalanx of little finger (digit 5)	Extends little finger (digit 5)	Deep radial nerve (C ₆ –C ₈)
Flexor digitorum superficialis	Medial epicondyle of humerus; adjacent anterior surfaces of ulna and radius	Midlateral surfaces of middle phalanges of digits 2–5	Flexes hand and middle fingers (digits 2-5)	Median nerve (C ₇ –T ₁)
Flexor digitorum profundus	Medial and posterior surfaces of ulna, medial surface of coronoid process, and interosseous membrane	Bases of distal phalanges of digits 2–5	Flexes hand and middle fingers (digits 2-5)	Palmar interosseous nerve, from median nerve, and ulnar nerve (C ₈ –T ₁)
Flexor pollicis longus	Anterior shaft of radius, interosseous membrane	Base of distal phalanx of thumb	Flexes distal phalanx of thumb	Median nerve (C ₈ –T ₁)

*Where appropriate, spinal nerves involved are given in parentheses.

notice that, in general, the extensor muscles lie along the posterior and lateral surfaces of the arm, whereas the flexors are on the anterior and medial surfaces. Connective tissue partitions separate major muscle groups, dividing the muscles into *compartments* formed by dense collagenous sheets.

The **brachialis** and **brachioradialis** (BRĀ-kē-ō-rā-dē-AH-lis) flex the elbow and are opposed by the **anconeus** and the **triceps brachii**, respectively.

Supination and Pronation. Supination and pronation involve changes in the relationship between the bones of the forearm, the radius and ulna. Such changes also result in movement of the palm of the hand. For this reason, the muscles involved in supination and pronation are shown in **Figure 11-18e**. The **supinator** and **pronator teres** originate on both the humerus and ulna. These muscles rotate the radius without either flexing or extending the elbow. The square-shaped **pronator quadratus** originates on the ulna and assists the pronator teres in opposing the actions of the supinator or biceps brachii. During pronation, the tendon of the biceps brachii rotates with the radius. As a result, this muscle cannot assist in flexion of the elbow when the forearm is pronated.

Action at the Wrist. The **flexor carpi ulnaris**, **flexor carpi radialis**, and **palmaris longus** are superficial muscles that work together to produce flexion of the wrist. The flexor carpi radialis flexes and *abducts*, and the flexor carpi ulnaris flexes

and *adducts*. *Pitcher's arm* is an inflammation at the origins of the flexor carpi muscles at the medial epicondyle of the humerus. This condition results from forcibly flexing the wrist just before releasing a baseball.

The **extensor carpi radialis** and the **extensor carpi ulnaris** have a similar relationship to that between the flexor carpi muscles. That is, the extensor carpi radialis produces extension and *abduction*, whereas the extensor carpi ulnaris produces extension and *adduction*.

Refer to the detailed summary listed in **Table 11-13** and compare it with the illustrations in **Figure 11-17** and **Figure 11-18e**.

Several superficial and deep muscles of the forearm flex and extend the finger joints (**Figure 11-18** and **Table 11-14**). These large muscles end before reaching the wrist, and only their tendons cross the articulation. This arrangement ensures maximum mobility at both the wrist and hand. The tendons that cross the posterior and anterior surfaces of the wrist pass through **synovial tendon sheaths**, elongated bursae that reduce friction.

The fascia of the forearm thickens on the posterior surface of the wrist, forming the **extensor retinaculum** (ret-i-NAK-ū-lum; plural, *retinacula*), a wide band of connective tissue. The extensor retinaculum holds the tendons of the extensor muscles in place. On the anterior surface, the fascia also thickens to form another wide band of connective tissue, the

Figure 11–19 Intrinsic Muscles of the Hand.

Which two intrinsic thumb muscles are an agonist–antagonist pair?

Table 11–15 Intrinsic Muscles of the Hand (Figure 11–19)

Muscle	Origin	Insertion	Action	Innervation*
Palmaris brevis	Palmar aponeurosis	Skin of medial border of hand	Moves skin on medial border toward midline of palm	Ulnar nerve, superficial branch (C ₈)
ADDUCTION/ABDUCTION				
Adductor pollicis	Metacarpal and carpal bones	Proximal phalanx of thumb	Adducts thumb	Ulnar nerve, deep branch (C ₈ –T ₁)
Palmar interossei**	Sides of metacarpal bones II, IV, and V	Bases of proximal phalanges of fingers 2, 4, and 5	Adduction at metacarpophalangeal joints of fingers 2, 4, and 5; flexion at metacarpophalangeal joints; extension at interphalangeal joints	Ulnar nerve, deep branch (C ₈ –T ₁)
Abductor pollicis brevis	Transverse carpal ligament, scaphoid, and trapezium	Radial side of base of proximal phalanx of thumb	Abducts thumb	Median nerve (C ₆ –C ₇)
Dorsal interosseus (4)	Each originates from opposing faces of two metacarpal bones (I and II, II and III, III and IV, IV and V)	Bases of proximal phalanges of fingers 2–4	Abduction at metacarpophalangeal joints of fingers 2 and 4; flexion at metacarpophalangeal joints; extension at interphalangeal joints	Ulnar nerve, deep branch (C ₈ –T ₁)
Abductor digiti minimi	Pisiform	Proximal phalanx of little finger	Abduction and flexion of little finger (digit 5) at its metacarpophalangeal joint	Ulnar nerve, deep branch (C ₈ –T ₁)
FLEXION				
Flexor pollicis brevis**	Flexor retinaculum, trapezium, capitate, and ulnar side of first metacarpal bone	Radial and ulnar sides of proximal phalanx of thumb	Flexes thumb	Branches of median and ulnar nerves
Lumbricals (4)	Tendons of flexor digitorum profundus	Tendons of extensor digitorum to digits 2–5	Flexion at metacarpophalangeal joints 2–5; extension at proximal and distal interphalangeal joints, digits 2–5	Median nerve (lumbricals 1 and 2); ulnar nerve, deep branch (lumbricals 3 and 4)
Flexor digiti minimi brevis	Hamate	Proximal phalanx of little finger	Flexion at joints of little finger (digit 5)	Ulnar nerve, deep branch (C ₈ –T ₁)
OPPOSITION				
Opponens pollicis	Trapezium and flexor retinaculum	First metacarpal bone	Opposition of thumb	Median nerve (C ₆ –C ₇)
Opponens digiti minimi	Trapezium and flexor retinaculum	Fifth metacarpal bone	Opposition of fifth metacarpal bone	Ulnar nerve, deep branch (C ₈ –T ₁)

*Where appropriate, spinal nerves involved are given in parentheses.

**The palmar interossei are a group of paired muscles between the metacarpals. There are four, sometimes three, palmar muscles that adduct fingers. The deep, medial portion of the flexor pollicis brevis originating on the first metacarpal bone is sometimes called the *first palmar interosseus muscle*; it inserts on the ulnar side of the phalanx and is innervated by the ulnar nerve.

flexor retinaculum, which stabilizes the tendons of the flexor muscles.

Inflammation of the retinacula and synovial tendon sheaths can restrict movement and put pressure on the distal portions of the *median nerve*, a mixed (sensory and motor) nerve that innervates the hand. This condition, known as *carpal tunnel syndrome*, causes tingling, numbness, weakness, and chronic pain. A common cause is repetitive hand or wrist movements.

Before going on, compare **Figure 11–18** with the information summarized in **Table 11–14**.

Muscles That Move the Fingers and Thumb

The muscles of the forearm provide strength and gross motor movement of the hand and fingers. These muscles are known

as the *extrinsic muscles of the hand*. Fine motor movement of the hand involves small *intrinsic muscles*, which originate on the carpal and metacarpal bones. No muscles originate on the phalanges, and only tendons extend across the distal joints of the fingers and thumb. The intrinsic muscles of the hand are detailed in **Figure 11–19** and **Table 11–15**.

Muscles of the Pelvis and Lower Limbs

The pelvic girdle is tightly bound to the axial skeleton, permitting little movement. Few muscles of the axial musculature can influence the position of the pelvis. However, the muscles that position the lower limbs provide a range of movements in these limbs. These muscles can be divided into three functional

Table 11–16 Muscles That Move the Thigh (Figure 11–20)

Group and Muscle	Origin	Insertion	Action	Innervation*
GLUTEAL GROUP				
Gluteus maximus	Iliac crest, posterior gluteal line, and lateral surface of ilium; sacrum, coccyx, and thoracolumbar fascia	Iliotibial tract and gluteal tuberosity of femur	Extends and laterally rotates hip	Inferior gluteal nerve (L ₅ –S ₂)
Gluteus medius	Anterior iliac crest of ilium, lateral surface between posterior and anterior gluteal lines	Greater trochanter of femur	Abducts and medially rotates hip	Superior gluteal nerve (L ₄ –S ₁)
Gluteus minimus	Lateral surface of ilium between inferior and anterior gluteal lines	Greater trochanter of femur	Abduction and medial rotation at hip	Superior gluteal nerve (L ₄ –S ₁)
Tensor fasciae latae	Iliac crest and lateral surface of anterior superior iliac spine	Iliotibial tract	Extension of the knee and lateral rotation of the leg acting through the iliotibial tract; weak roles in abduction and medial rotation of the thigh	Superior gluteal nerve (L ₄ –S ₁)
LATERAL ROTATOR GROUP				
Obturator (externus and internus)	Lateral and medial margins of obturator foramen	Trochanteric fossa of femur (externus); medial surface of greater trochanter (internus)	Lateral rotation at hip	Obturator nerve (externus: L ₃ –L ₄) and special nerve from sacral plexus (internus: L ₅ –S ₂)
Piriformis	Anterolateral surface of sacrum	Greater trochanter of femur	Lateral rotation and abduction at hip	Branches of sacral nerves (S ₁ –S ₂)
Gemellus (superior and inferior)	Ischial spine and tuberosity	Medial surface of greater trochanter with tendon of obturator internus	Lateral rotation at hip	Nerves to obturator internus and quadratus femoris
Quadratus femoris	Lateral border of ischial tuberosity	Intertrochanteric crest of femur	Lateral rotation at hip	Special nerve from sacral plexus (L ₄ –S ₁)
ADDUCTOR GROUP				
Adductor brevis	Inferior ramus of pubis	Linea aspera of femur	Adduction, flexion, and medial rotation at hip	Obturator nerve (L ₃ –L ₄)
Adductor longus	Inferior ramus of pubis anterior to adductor brevis	Linea aspera of femur	Adduction, flexion, and medial rotation at hip	Obturator nerve (L ₃ –L ₄)
Adductor magnus	Inferior ramus of pubis posterior to adductor brevis and ischial tuberosity	Linea aspera and adductor tubercle of femur	Adduction at hip; superior part produces flexion and medial rotation; inferior part produces extension and lateral rotation	Obturator and sciatic nerves
Pectineus	Superior ramus of pubis	Pectineal line inferior to lesser trochanter of femur	Flexion, medial rotation, and adduction at hip	Femoral nerve (L ₂ –L ₄)
Gracilis	Inferior ramus of pubis	Medial surface of tibia inferior to medial condyle	Flexion at knee; adduction and medial rotation at hip	Obturator nerve (L ₃ –L ₄)
ILIOPSOAS GROUP**				
Iliacus	Iliac fossa of ilium	Femur distal to lesser trochanter; tendon fused with that of psoas major	Flexion at hip	Femoral nerve (L ₂ –L ₃)
Psoas major	Anterior surfaces and transverse processes of vertebrae (T ₁₂ –L ₅)	Lesser trochanter in company with iliacus	Flexion at hip or lumbar intervertebral joints	Branches of the lumbar plexus (L ₂ –L ₃)

*Where appropriate, spinal nerves involved are given in parentheses.

**The iliacus and psoas major are often considered collectively as the iliopsoas.

groups: (1) *muscles that move the thigh*, (2) *muscles that move the leg*, and (3) *muscles that move the foot and toes*.

Muscles That Move the Thigh

Gluteal muscles cover the lateral surfaces of the ilia (Figure 11–20a,b,c). The **gluteus maximus** is the largest and most posterior of the gluteal muscles. Its origin includes parts

of the ilium; the sacrum and coccyx; and the thoracolumbar fascia. Acting alone, this massive muscle produces extension and lateral rotation at the hip joint (Table 11–16).

The gluteus maximus shares an insertion with the **tensor fasciae latae** (FASH-ē-ē LAH-tā), which originates on the iliac crest and the anterior superior iliac spine. Together, these muscles pull on the **iliotibial** (il-ē-ō-TIB-ē-ul) **tract**, a band

Figure 11–20 Muscles That Move the Thigh.

Table 11-17 Muscles That Move the Leg (Figure 11-21)

Muscle	Origin	Insertion	Action	Innervation*
FLEXORS OF THE KNEE				
Biceps femoris	Ischial tuberosity and linea aspera of femur	Head of fibula, lateral condyle of tibia	Flexion at knee; extension and lateral rotation at hip	Sciatic nerve; tibial portion (S ₁ –S ₃ ; to long head) and common fibular branch (L ₅ –S ₂ ; to short head)
Semitendinosus	Ischial tuberosity	Proximal, medial surface of tibia near insertion of gracilis	Flexion at knee; extension and medial rotation at hip	Sciatic nerve (tibial portion; L ₅ –S ₂)
Semimembranosus	Ischial tuberosity	Posterior surface of medial condyle of tibia	Flexion at knee; extension and medial rotation at hip	Sciatic nerve (tibial portion; L ₅ –S ₂)
Sartorius	Anterior superior iliac spine	Medial surface of tibia near tibial tuberosity	Flexion at knee; flexion and lateral rotation at hip	Femoral nerve (L ₂ –L ₃)
Popliteus	Lateral condyle of femur	Posterior surface of proximal tibial shaft	Medial rotation at tibia (or lateral rotation of femur); flexion at knee	Tibial nerve (L ₄ –S ₁)
EXTENSORS OF THE KNEE				
Rectus femoris	Anterior inferior iliac spine and superior acetabular rim of ilium	Tibial tuberosity by patellar ligament	Extension at knee; flexion at hip	Femoral nerve (L ₂ –L ₄)
Vastus intermedius	Anterolateral surface of femur and linea aspera (distal half)	Tibial tuberosity by patellar ligament	Extension at knee	Femoral nerve (L ₂ –L ₄)
Vastus lateralis	Anterior and inferior to greater trochanter of femur and along linea aspera (proximal half)	Tibial tuberosity by patellar ligament	Extension at knee	Femoral nerve (L ₂ –L ₄)
Vastus medialis	Entire length of linea aspera of femur	Tibial tuberosity by patellar ligament	Extension at knee	Femoral nerve (L ₂ –L ₄)

*Where appropriate, spinal nerves involved are given in parentheses.

of collagen fibers that extends along the lateral surface of the thigh and inserts on the tibia. This tract provides a lateral brace for the knee that becomes particularly important when balancing on one foot.

The **gluteus medius** and **gluteus minimus** (Figure 11-20a,b,c) originate anterior to the origin of the gluteus maximus and insert on the greater trochanter of the femur. The anterior gluteal line on the lateral surface of the ilium marks the boundary between these muscles.

The **lateral rotators** originate at or inferior to the horizontal axis of the acetabulum. There are six lateral rotator muscles in all. The **piriformis** (pir-i-FOR-mis) and the **obturator** are dominant (Figure 11-20c,d).

The **adductors** (Figure 11-20c,d) originate inferior to the horizontal axis of the acetabulum. This muscle group includes the **pectineus** (pek-ti-NĒ-us), **adductor magnus**, **adductor brevis**, **adductor longus**, and **gracilis** (GRAS-i-lis). All but the adductor magnus originate both anterior and inferior to the joint, so they perform hip flexion as well as adduction. The adductor magnus can produce either adduction and flexion or adduction and extension, depending on the region stimulated. The adductor magnus can also produce medial or lateral rotation at the hip. The other muscles, which insert on low ridges along the posterior surface of the femur, produce medial rotation. When an athlete experiences a *pulled groin*, the problem is a *strain*—a muscle tear—in one of these adductor muscles.

A pair of muscles controls the internal surface of the pelvis. The large **psoas** (SŌ-us) **major** originates alongside the inferior thoracic and lumbar vertebrae. Its insertion lies on the lesser trochanter of the femur. Before reaching this insertion, its tendon merges with that of the **iliacus** (il-Ī-ah-kus), which nestles within the iliac fossa. These two powerful hip flexors are often grouped together and collectively referred to as the **iliopsoas** (il-ē-ō-SŌ-us) (Figure 11-20d).

Compare Figure 11-20 with Table 11-16 to understand the muscles that move the thigh.

Muscles That Move the Leg

As in the upper limb, muscle distribution in the lower limb has a pattern: Extensor muscles are located along the anterior and lateral surfaces of the leg, and flexors lie along the posterior and medial surfaces (Figure 11-21). As in the upper limb, sturdy connective tissue partitions divide the lower limb into separate muscular compartments. The flexors and adductors originate on the pelvic girdle, but most extensors originate on the femoral surface.

The *flexors of the knee* include the **biceps femoris**, **semitendinosus** (sem-ē-ten-di-NŌ-sus), **semimembranosus** (sem-ē-mem-bra-NŌ-sus), and **sartorius** (Figure 11-21a and Table 11-17). These muscles originate along the edges of the pelvis and insert on the tibia and fibula. The sartorius is the only knee flexor that originates superior to the acetabulum. Its insertion lies along the medial surface of the tibia. The sartorius crosses over two joints and its contraction produces

Figure 11–21 Muscles That Move the Leg.

Which quadriceps femoris muscle is not visible from the superficial anterior thigh view?

Table 11–18 Extrinsic Muscles That Move the Foot and Toes (Figure 11–22)

Muscle	Origin	Insertion	Action	Innervation*
ACTION AT THE ANKLE				
<i>Flexors (dorsiflexors)</i>				
Tibialis anterior	Lateral condyle and proximal shaft of tibia	Base of first metatarsal bone and medial cuneiform bone	Flexion (dorsiflexion) at ankle; inversion of foot	Deep fibular nerve (L ₄ –S ₁)
Fibularis tertius	Distal anterior surface of fibula and interosseous membrane	Dorsal surface of fifth metatarsal bone	Flexion (dorsiflexion) at ankle; eversion of foot	Deep fibular nerve (L ₅ –S ₁)
<i>Extensors (plantar flexors)</i>				
Gastrocnemius	Femoral condyles	Calcaneus by calcaneal tendon	Extension (plantar flexion) at ankle; inversion of foot; flexion at knee	Tibial nerve (S ₁ –S ₂)
Fibularis brevis	Midlateral margin of fibula	Base of fifth metatarsal bone	Eversion of foot and extension (plantar flexion) at ankle	Superficial fibular nerve (L ₄ –S ₁)
Fibularis longus	Lateral condyle of tibia, head and proximal shaft of fibula	Base of first metatarsal bone and medial cuneiform bone	Eversion of foot and extension (plantar flexion) at ankle; supports longitudinal arch	Superficial fibular nerve (L ₄ –S ₁)
Plantaris	Lateral supracondylar ridge	Posterior portion of calcaneus	Extension (plantar flexion) at ankle; flexion at knee	Tibial nerve (L ₄ –S ₁)
Soleus	Head and proximal shaft of fibula and adjacent posteromedial shaft of tibia	Calcaneus by calcaneal tendon (with gastrocnemius)	Extension (plantar flexion) at ankle	Sciatic nerve, tibial branch (S ₁ –S ₂)
Tibialis posterior	Interosseous membrane and adjacent shafts of tibia and fibula	Tarsal and metatarsal bones	Adduction and inversion of foot; extension (plantar flexion) at ankle	Sciatic nerve, tibial branch (S ₁ –S ₂)
ACTION AT THE TOES				
<i>Digital flexors</i>				
Flexor digitorum longus	Posteromedial surface of tibia	Inferior surfaces of distal phalanges, toes 2–5	Flexion at joints of toes 2–5	Sciatic nerve, tibial branch (L ₅ –S ₁)
Flexor hallucis longus	Posterior surface of fibula	Inferior surface, distal phalanx of great toe	Flexion at joints of great toe	Sciatic nerve, tibial branch (L ₅ –S ₁)
<i>Digital extensors</i>				
Extensor digitorum longus	Lateral condyle of tibia, anterior surface of fibula	Superior surfaces of phalanges, toes 2–5	Extension at joints of toes 2–5	Deep fibular nerve (L ₄ –S ₁)
Extensor hallucis longus	Anterior surface of fibula	Superior surface, distal phalanx of great toe	Extension at joints of great toe	Deep fibular nerve (L ₄ –S ₁)

*Where appropriate, spinal nerves involved are given in parentheses.

flexion at the knee and lateral rotation at the hip. This happens when a person crosses their legs.

Three of these muscles—the biceps femoris, semitendinosus, and semimembranosus—are often called the **hamstrings**. Because they originate on the pelvic surface inferior and posterior to the acetabulum, their contractions produce not only flexion at the knee, but also extension at the hip. A *pulled hamstring* is a common sports injury caused by a strain affecting one of the hamstring muscles.

Tips

To remember that three muscles make up the **hamstrings**, think “the three little pigs.” These three muscles are portions of the cut of meat known as ham.

The knee joint can be locked at full extension by a slight lateral rotation of the tibia. The small **popliteus** (pop-LI-tē-us) originates on the femur near the lateral condyle and inserts on the posterior tibial shaft (**Figure 11–22a**). When flexion is started, this muscle contracts to produce a slight medial rotation of the tibia that unlocks the knee joint.

Collectively, four *knee extensors*—the three **vastus muscles**, which originate along the shaft of the femur, and the **rectus femoris**—make up the **quadriceps femoris** (the “quads”). Together, the vastus muscles cradle the rectus femoris the way a bun surrounds a hot dog (**Figure 11–21c**). All four muscles insert on the patella by way of the quadriceps tendon. The force of their contraction is relayed to the tibial tuberosity by way of the patellar ligament. The rectus femoris originates on the anterior inferior iliac spine and the superior acetabular

Figure 11–22 Extrinsic Muscles That Move the Foot and Toes.

+ Clinical Note Hernia

When the abdominal muscles contract forcefully, pressure in the abdominopelvic cavity can increase dramatically, applying pressure to internal organs. If the person exhales at the same time, the pressure is relieved because the diaphragm, the muscle that separates the thoracic and abdominopelvic cavities, can move upward as the lungs deflate. But during vigorous isometric exercises or when lifting a weight while holding one's breath, pressure in the abdominopelvic cavity can rise to about 100 times the normal pressure. A pressure that high can cause a hernia. A **hernia** develops when a visceral organ or part of an organ protrudes abnormally through an opening in a surrounding muscular wall. There are many types of hernias. Here we consider only *inguinal* (groin) *hernias* and *diaphragmatic hernias*.

In adult males, the spermatic cords penetrate the abdominal musculature through the inguinal canals on their way to the abdominal reproductive organs. In an **inguinal hernia**, the inguinal canal enlarges, and organs, such as a portion of the intestine, or (more rarely) urinary bladder, enter the inguinal canal. If these structures become trapped or twisted, surgery may be required.

In a **diaphragmatic hernia**, abdominal organs protrude through a weakness in the diaphragm. If these organs protrude through the *esophageal hiatus*, the passageway used by the esophagus, a *hiatal hernia* (hī-Ā-tul; *hiatus*, opening) exists. Hiatal hernias are very common. Most go unnoticed, although they may increase the gastric acid entry into the esophagus, causing *heartburn*.

rim—so in addition to extending the knee, it assists in flexion of the hip.

Tips

Think of the quadriceps femoris as “the four at the fore.”

Now compare the illustrations in **Figure 11-21** with the summary of these muscles in **Table 11-17**.

Muscles That Move the Foot and Toes

The extrinsic muscles that move the foot and toes are shown in **Figure 11-22** and summarized in **Table 11-18**. Most of the muscles that move the ankle produce the plantar flexion involved with walking and running movements. The **gastrocnemius** (gas-trok-NĒ-mĒ-us; *gaster*, stomach + *kneme*, knee) of the calf is an important plantar flexor, but the slow muscle

fibers of the underlying **soleus** (SŌ-lĒ-us) are better suited for making continuous postural adjustments against the pull of gravity.

These muscles are best seen in posterior and lateral views (**Figure 11-22a,b**). The gastrocnemius arises from two heads located on the medial and lateral epicondyles of the femur just proximal to the knee. The *fabella*, a sesamoid bone, is occasionally present in the tendon of the lateral head of the gastrocnemius.

Tips

The **soleus** is so named because it resembles the flat-bodied fish we call sole.

The gastrocnemius and soleus share a common tendon, the **calcaneal tendon**, known as the *Achilles tendon*.

Table 11–19 Intrinsic Muscles of the Foot (Figure 11–23)

Muscle	Origin	Insertion	Action	Innervation*
FLEXION/EXTENSION				
Flexor hallucis brevis	Cuboid and lateral cuneiform bones	Proximal phalanx of great toe	Flexion at metatarsophalangeal joint of great toe	Medial plantar nerve (L ₄ –L ₅)
Flexor digitorum brevis	Calcaneus (tuberosity on inferior surface)	Sides of middle phalanges, toes 2–5	Flexion at proximal interphalangeal joints of toes 2–5	Medial plantar nerve (L ₄ –L ₅)
Quadratus plantae	Calcaneus (medial, inferior surfaces)	Tendon of flexor digitorum longus	Flexion at joints of toes 2–5	Lateral plantar nerve (L ₄ –L ₅)
Lumbricals (4)	Tendons of flexor digitorum longus	Tendons of extensor digitorum longus	Flexion at metatarsophalangeal joints; extension at proximal interphalangeal joints of toes 2–5	Medial plantar nerve (lumbrical 1), lateral plantar nerve (lumbricals, 2, 3, and 4)
Flexor digiti minimi brevis	Base of metatarsal bone V	Lateral side of proximal phalanx of toe 5	Flexion at metatarsophalangeal joint of toe 5	Lateral plantar nerve (S ₁ –S ₂)
Extensor digitorum brevis	Calcaneus (superior and lateral surfaces)	Dorsal surfaces of toes 1–4	Extension at metatarsophalangeal joints of toes 1–4	Deep fibular nerve (L ₅ –S ₁)
Extensor hallucis brevis	Superior surface of anterior calcaneus	Dorsal surface of the base of proximal phalanx of great toe	Extension of great toe	Deep fibular nerve (L ₅ –S ₁)
ADDUCTION/ABDUCTION				
Adductor hallucis	Bases of metatarsal bones II–IV and plantar ligaments	Proximal phalanx of great toe	Adduction at metatarsophalangeal joint of great toe	Lateral plantar nerve (S ₁ –S ₂)
Abductor hallucis	Calcaneus (tuberosity on inferior surface)	Medial side of proximal phalanx of great toe	Abduction at metatarsophalangeal joint of great toe	Medial plantar nerve (L ₄ –L ₅)
Plantar interosseus (3)	Bases and medial sides of metatarsal bones	Medial sides of toes 3–5	Adduction at metatarsophalangeal joints of toes 3–5	Lateral plantar nerve (S ₁ –S ₂)
Dorsal interosseus (4)	Sides of metatarsal bones	Medial and lateral sides of toe 2; lateral sides of toes 3 and 4	Abduction at metatarsophalangeal joints of toes 3 and 4	Lateral plantar nerve (S ₁ –S ₂)
Abductor digiti minimi	Inferior surface of calcaneus	Lateral side of proximal phalanx, toe 5	Abduction at metatarsophalangeal joint of toe 5	Lateral plantar nerve (L ₄ –L ₅)

*Where appropriate, spinal nerves involved are given in parentheses.

This term comes from Greek mythology, as Achilles was a warrior who was invincible but for one vulnerable spot: the calcaneal tendon. Outside mythology, damage to the calcaneal tendon isn't a fatal problem. Although it is among the largest, strongest tendons in the body, its rupture is common. The applied forces increase markedly during rapid acceleration or deceleration. Sprinters can rupture the calcaneal tendon pushing off from starting blocks, and this tendon can be snapped during a stumble or fall. Surgery may be necessary to reposition and reconnect the torn ends of the tendon to promote healing.

Deep to the gastrocnemius and soleus are a pair of **fibularis** muscles, longus and brevis, or *peroneus* (Figure 11–22a,b). The fibularis produces eversion and extension (plantar flexion) at the ankle. Inversion is caused by the contraction of the **tibialis** (tib-ĕ-AH-lis) muscles. The

large **tibialis anterior** flexes the ankle and opposes the gastrocnemius (Figure 11–22b,c).

Important digital muscles originate on the surface of the tibia, the fibula, or both (Figure 11–22c,d). Large synovial tendon sheaths surround the tendons of the tibialis anterior, **extensor digitorum longus**, and **extensor hallucis longus**, where they cross the ankle joint. The positions of these sheaths are stabilized by superior and inferior **extensor retinacula**.

The summary listed in Table 11–18 can be compared with Figure 11–22 for a more complete understanding of these muscles.

Intrinsic muscles of the foot originate on the tarsal and metatarsal bones (Figure 11–23 and Table 11–19). Their contractions move the toes and maintain the longitudinal arch of the foot.

Figure 11–23 Intrinsic Muscles of the Foot.**a Dorsal view****b Plantar view, superficial layer****c Plantar view, deep layer**

✓ Checkpoint

19. A person shrugging their shoulders uses which muscles?
20. Baseball pitchers sometimes develop rotator cuff injuries. Which muscles are involved in this type of injury?
21. An injury to the flexor carpi ulnaris would impair which two movements?
22. Which leg movement would be impaired by injury to the obturator?
23. To what does a “pulled hamstring” refer?
24. How would a torn calcaneal tendon affect movement of the foot?

See the blue Answers tab at the back of the book.

11-8 Exercise of the muscular system produces responses in multiple body systems

Learning Outcome Explain the functional relationship between the muscular system and other body systems and explain the role of exercise in producing various responses in other body systems.

To operate at maximum efficiency, the muscular system must be supported by many other systems. The changes that take place during exercise provide a good example of such interaction. As noted earlier, active muscles consume oxygen and generate carbon dioxide and heat. The immediate effects of exercise on various body systems include the following:

- *Cardiovascular System:* Heart rate increases, and blood vessels in active muscles and the skin dilate. These adjustments speed up oxygen and nutrient delivery to

and carbon dioxide removal from the muscle. They also bring heat to the skin for radiation into the environment.

- *Respiratory System:* Respiratory rate and depth of respiration increase. Air moves into and out of the lungs more quickly, keeping pace with the increased rate of blood flow through the lungs.
- *Integumentary System:* Blood vessels dilate and sweat gland secretion increases. This combination increases evaporation at the skin surface and removes the excess heat generated by muscular activity.
- *Nervous and Endocrine Systems:* The responses of other systems are directed and coordinated through neural and endocrine (hormonal) adjustments in heart rate, respiratory rate, sweat gland activity, and mobilization of stored nutrient reserves.

Even when the body is at rest, the muscular system has extensive interactions with other systems. Build Your Knowledge **Figure 11-24** summarizes the range of interactions between the muscular system and other body systems studied so far.

✓ Checkpoint

25. What major function does the muscular system perform for the body as a whole?
26. Identify the physiological effects of exercise on the cardiovascular, respiratory, and integumentary systems, and indicate the relationship between those physiological effects and the nervous and endocrine systems.

See the blue Answers tab at the back of the book.

Build Your Knowledge

Figure 11–24 Integration of the MUSCULAR system with the other body systems presented so far.

Integumentary System

- The Integumentary System removes excess body heat, synthesizes vitamin D₃ for calcium and phosphate absorption, and protects underlying muscles.
- The muscular system includes facial muscles that pull on the skin of the face to produce facial expressions

Skeletal System

- The Skeletal System provides mineral reserves for maintaining normal calcium and phosphate levels in body fluids, supports skeletal muscles, and provides sites of muscle attachment.
- The muscular system provides skeletal movement and support, and stabilizes bones and joints. Stresses exerted by tendons maintain normal bone structure and bone mass.

Muscular System

The Muscular System performs these primary functions for the human body:

- It produces skeletal movement
- It helps maintain posture and body position
- It supports soft tissues
- It guards entrances and exits to the body
- It helps maintain body temperature

11 Chapter Review

Study Outline

An Introduction to the Muscular System

1. Structural variations among skeletal muscles affect their power, range, and speed of movement.

11-1 Fascicle arrangement is correlated with muscle power and range of motion

2. A muscle can be classified as a **parallel muscle**, **convergent muscle**, **pennate muscle**, or **circular muscle (sphincter)** according to its arrangement of fascicles. A pennate muscle may be *unipennate*, *bipennate*, or *multipennate*. (Figure 11-1)

11-2 The use of bones as levers increases muscle efficiency

3. A **lever** is a rigid structure that moves around a fixed point called the **fulcrum**. Levers can change the direction and effective strength of an applied force, and the distance and speed of the movement such a force produces.
4. Levers are classified as **first-class**, **second-class**, or **third-class levers** based on the relative position of three elements: applied force (AF), fulcrum (F), and load (L). Third-class levers are the most common levers in the body. (Figure 11-2)

11-3 The origins and insertions of muscles determine their actions

5. Each muscle can be identified by its *origin*, *insertion*, and *action*.
6. The site of attachment of the fixed end of a muscle is called the **origin**; the site where the movable end of the muscle attaches to another structure is called the **insertion**.
7. A muscle's **action** is the movement produced when it contracts. (Spotlight Figure 11-3)
8. According to the function of its action, a muscle can be classified as an **agonist**, or **prime mover**; an **antagonist**; a **synergist**; or a **fixator**.

11-4 Descriptive terms are used to name skeletal muscles

9. The names of muscles commonly provide clues to their body region, origin and insertion, fascicle arrangement, position, structural characteristics, and action. (Table 11-1)

11-5 Axial muscles position the axial skeleton, and appendicular muscles support and move the appendicular skeleton

10. The **axial musculature** arises on the axial skeleton; it positions the head and vertebral column and moves the rib cage. The **appendicular musculature** stabilizes or moves the limbs of the appendicular skeleton. (Figure 11-4)
11. **Innervation** refers to the distribution of nerves that control a region or organ, including a muscle.

- PhysioEx

11-6 Axial muscles are muscles of the head and neck, vertebral column, trunk, and pelvic floor

12. The axial muscles fall into logical groups based on location, function, or both.
13. Important muscles of facial expression include the **orbicularis oris**, **buccinator**, **occipitofrontalis**, and **platysma**. (Figure 11-5; Table 11-2)
14. Six extrinsic eye muscles (*oculomotor muscles*) control eye movements: the **inferior** and **superior rectus**, the **lateral** and **medial rectus**, and the **inferior** and **superior oblique**. (Figure 11-6; Table 11-3)
15. The muscles of mastication (chewing) are the **masseter**, **temporalis**, and **pterygoid** muscles. (Figure 11-7; Table 11-4)
16. The four muscles of the tongue are necessary for speech and swallowing and assist in mastication. They are the **palatoglossus**, **styloglossus**, **genioglossus**, and **hyoglossus**. (Figure 11-8; Table 11-5)
17. The muscles of the pharynx constrict the pharyngeal walls (**pharyngeal constrictors**), raise the larynx (**laryngeal elevators**), or raise the soft palate (**palatal muscles**). (Figure 11-9; Table 11-6)
18. The anterior muscles of the neck control the position of the larynx, depress the mandible, and provide a foundation for the muscles of the tongue and pharynx. The neck muscles include the **digastric** and **sternocleidomastoid** and seven muscles that originate or insert on the hyoid bone. (Figure 11-10; Table 11-7)
19. The superficial muscles of the spine can be classified into the **spinalis**, **longissimus**, and **iliocostalis** groups. (Figure 11-11; Table 11-8)
20. Other muscles of the spine include the **longus capitis** and **longus colli** of the neck, the small intervertebral muscles of the deep layer, and the **quadratus lumborum** of the lumbar region. (Figure 11-11; Table 11-8)
21. The oblique muscles include the **scalene** muscles and the **intercostal** and **transversus** muscles. The **external** and **internal intercostal muscles** are important in respiratory (breathing) movements of the ribs. Also important to respiration is the **diaphragm**. (Figures 11-11, 11-12; Table 11-9)
22. The **perineum** can be divided into an anterior **urogenital triangle** and a posterior **anal triangle**. The pelvic floor contains the muscles comprising the **pelvic diaphragm**. (Figure 11-13; Table 11-10)

11-7 Appendicular muscles are muscles of the shoulders, upper limbs, pelvis, and lower limbs

23. The **trapezius** affects the positions of the shoulder girdle, head, and neck. Other muscles inserting on the scapula include the **rhomboid**, **levator scapulae**, **serratus anterior**, **subclavius**, and **pectoralis minor**. (Figures 11-14, 11-16; Table 11-11)
24. Among muscles that move the arm, the **deltoid** and the **supraspinatus** are important abductors. The **subscapularis** and **teres major** produce medial rotation at the shoulder; the **infraspinatus** and **teres minor** produce lateral rotation; and the **coracobrachialis** produces flexion and adduction at the shoulder. (Figures 11-14 to 11-16; Table 11-12)
25. The **pectoralis major** flexes the shoulder joint, and the **latissimus dorsi** extends it. (Figures 11-14 to 11-16; Table 11-12)
26. Among muscles that move the forearm and hand, the actions of the **biceps brachii** and the **triceps brachii** (long head) affect the elbow joint. The **brachialis** and **brachioradialis** flex the elbow, opposed by the **anconeus**. The **flexor carpi ulnaris**, **flexor carpi radialis**, and **palmaris longus** cooperate to flex the wrist. The **extensor carpi radialis** and the **extensor carpi ulnaris** oppose them. The **pronator teres** and **pronator quadratus** pronate the forearm and are opposed by the **supinator**. (Figures 11-16 to 11-19; Tables 11-13 to 11-15)
27. Among muscles that move the thigh, **gluteal muscles** cover the lateral surfaces of the ilia. The largest is the **gluteus maximus**, which shares an insertion with the **tensor fasciae latae**. Together, these muscles pull on the **iliotibial tract**. (Figure 11-20; Table 11-16)

28. The **piriformis** and the **obturator** are the most important **lateral rotators**. The **adductors** can produce a variety of movements. (Figure 11-20; Table 11-16)
29. The **psoas major** and **iliacus** merge to form the **iliopsoas**, a powerful flexor of the hip. (Figures 11-20, 11-21; Table 11-16)
30. Among muscles that move the leg, the flexors of the knee include the **biceps femoris**, **semimembranosus**, and **semitendinosus** (the three **hamstrings**) and the **sartorius**. The **popliteus** unlocks the knee joint. (Figures 11-21, 11-22a; Table 11-17)
31. Collectively, the knee extensors are known as the **quadriceps femoris**. This group consists of the three **vastus** muscles (intermedius, lateralis, medialis) and the **rectus femoris**. (Figure 11-21; Table 11-17)
32. Among muscles that move the foot and toes, the **gastrocnemius** and **soleus** produce plantar flexion (ankle extension). The **fibularis brevis** and **longus** produce eversion as well as extension (plantar flexion) at the ankle. The **fibularis tertius** produces eversion and flexion (dorsiflexion) at the ankle. (Figure 11-22; Table 11-18)
33. Smaller muscles of the calf and shin (tibia) position the foot and move the toes. Muscles originating at the tarsal and metatarsal bones provide precise control of the phalanges. (Figure 11-23; Table 11-19)

11-8 Exercise of the muscular system produces responses in multiple body systems

34. Exercise illustrates the integration of the muscular system with the cardiovascular, respiratory, integumentary, nervous, and endocrine systems. (Figure 11-24)

Review Questions

See the blue Answers tab at the back of the book.

LEVEL 1 Reviewing Facts and Terms

1. Name the three pennate muscles in the following figure, and for each muscle indicate the type of pennate muscle based on the relationship of muscle fascicles to the tendon.

- (a) _____
- (b) _____
- (c) _____

2. Label the three visible muscles of the rotator cuff in the following posterior view of the deep muscles that move the arm.

- (a) _____
- (b) _____
- (c) _____

3. The pectoralis is an example of a (a) parallel muscle, (b) circular muscle, (c) convergent muscle, (d) pennate muscle, (e) wrapping muscle.

4. Levers make action more versatile by all of the following, *except* (a) changing the location of the muscle's insertion, (b) changing the speed of movement produced by an applied force, (c) changing the distance of movement produced by an applied force, (d) changing the strength of an applied force, (e) changing the direction of an applied force.
5. The muscles whose lines of action cross the medial side of a joint are (a) flexors, (b) abductors, (c) extensors, (d) adductors, (e) rotators.
6. The muscles of mastication are innervated by cranial nerve (a) VII, (b) V, (c) IV, (d) VI.
7. The muscle that retracts and elevates the corner of the mouth is the (a) zygomaticus major, (b) zygomaticus minor, (c) risorius, (d) buccinator.
8. The muscle that depresses the soft palate is the (a) levator veli palatine, (b) palatoglossus, (c) hyoglossus, (d) tensor veli palatine.
9. Important flexors of the vertebral column that act in opposition to the erector spinae are the (a) rectus abdominis, (b) longus capitis, (c) longus colli, (d) scalene.
10. The muscles that cause flexion at the metacarpophalangeal joints 2–5 are the (a) dorsal interossei, (b) palmar interossei, (c) lumbricals, (d) extensor retinacula.
11. The muscles that rotate the radius without producing either flexion or extension of the elbow are the (a) brachialis and brachioradialis, (b) pronator teres and supinator, (c) biceps brachii and triceps brachii, (d) a, b, and c.
12. One of the muscles that rotates the shoulder medially is the (a) teres major, (b) teres minor, (c) infraspinatus, (d) coracobrachialis.
13. Knee extensors known as the quadriceps femoris consist of the (a) three vastus muscles and the rectus femoris, (b) biceps femoris, gracilis, and sartorius, (c) popliteus, iliopsoas, and gracilis, (d) gastrocnemius, tibialis, and peroneus.
14. List the possible actions that can be produced by a muscle at a joint.
15. What is an aponeurosis? Give two examples.
16. Which four muscle groups make up the axial musculature?
17. What three functions are accomplished by the muscles of the pelvic floor?
18. On which bones do the four rotator cuff muscles originate and insert?
19. Which five muscles form the adductor group of the lower limbs?

LEVEL 2 Reviewing Concepts

20. In a third-class lever, the relative position of the fulcrum (F), the applied force (AF), and the load (L) can be described as (a) L–F–AF, (b) F–L–AF, (c) F–AF–L, (d) L–AF–F.
21. Compartment syndrome can result from all of the following *except* (a) compressing a nerve in the wrist, (b) compartments swelling with blood due to an injury involving blood vessels, (c) torn ligaments in a given compartment, (d) pulled tendons in the muscles of a given compartment, (e) torn muscles in a particular compartment.
22. A thickened fascia holding the tendons of muscles in place is called a(n) _____.
23. Forcible wrist flexion, such as throwing a ball, can result in the development of a condition called _____.
24. The muscles of the vertebral column include many posterior extensors but few anterior flexors. Why?
25. Why does a convergent muscle exhibit more versatility when contracting than does a parallel muscle?
26. How do the trapezius and the rhomboid muscles act as fixators during flexion at the elbow?
27. Why is it difficult to lift a heavy object when the elbow is at full extension?
28. Which types of movements are affected when the hamstrings are injured?

LEVEL 3 Critical Thinking and Clinical Applications

29. Katja complains about frequently suffering a burning pain in the chest. Her physician suggests that Katja may have a hiatal hernia. What does the physician mean by that?
30. Sam injured his right facial nerve, and this resulted in the loss of control over some muscles. Which muscle would certainly *not* be one of them? (a) zygomaticus major, (b) orbicularis oris, (c) masseter, (d) orbicularis oculi, (e) zygomaticus minor.
31. While unloading her car trunk, Eva strains a muscle and as a result has difficulty moving her arm. The doctor in the emergency room tells her that she strained her pectoralis major. Eva tells you that she thought the pectoralis major was a chest muscle and doesn't understand what that has to do with her arm. What should you tell her?

CLINICAL CASE Wrap-Up Downward-Facing Dog

At his 3-month visit, the nurse practitioner evaluates Rick's gains following the regular, low-intensity yoga exercise program. She conducts a review of systems, with a focus on his musculoskeletal system. She is looking for improved muscular strength and increased range of motion at the joints. She'll also inquire about Rick's arthritis pain level and how successfully he is able to perform his ADLs, or activities of daily living.

She observes that his muscle tone has improved overall. He can flex and extend more freely at joints in his arms and legs. He can get up from a chair and sit down with smoother motion than at the

last visit. He is still working on balance issues, but he can reach up and around, as in putting on his coat. "I was a gymnast for my college team, back in the day," Rick tells her. "This is the best I've felt in years!"

1. Look at the photo of the person executing downward-facing dog. Which muscles are contracting in this pose?
2. Which of Rick's muscles will help him maintain better posture as he goes about his day?

See the blue Answers tab at the back of the book.

Related Clinical Terms

charley horse: Common name for a muscle spasm, especially in the leg.

compartment syndrome: A condition in which increased pressure within the muscle compartment of a limb produces ischemia or “blood starvation.”

fibromyositis: Chronic illness characterized by widespread musculoskeletal aches, pains, and stiffness, and soft tissue tenderness.

groin pull: An injury that is due to a strain of the muscles of the inner thigh.

impingement syndrome: Pain on elevation of the shoulder due to an injured or inflamed tendon or bursa contacting the overlying acromial process.

11 physical therapist: Healthcare professional who uses specially designed exercises and equipment to help patients regain or improve their physical abilities.

plantar fasciitis: Inflammation of the plantar fascia causing foot or heel pain.

Poland syndrome: A congenital disorder characterized by a lack of muscle development on only one side of the body, primarily the pectoralis major muscle.

shin splints: Pain along the shinbone (tibia) caused by an overload on the tibia and connective tissues that connect muscle to the bone.

tenosynovitis: Inflammation of a tendon and the sheath that covers it.

torticollis: A shortening or contraction of the muscles of the neck resulting in the head being tipped to one side with the chin turned to the other side.

12

Nervous Tissue

Learning Outcomes

These Learning Outcomes correspond by number to this chapter's sections and indicate what you should be able to do after completing the chapter.

- 12-1 ■ Describe the anatomical and functional divisions of the nervous system.
- 12-2 ■ Sketch and label the structure of a typical neuron, describe the functions of each component, and classify neurons based on their structure and function.
- 12-3 ■ Describe the locations and functions of the various types of neuroglia.
- 12-4 ■ Explain how the resting membrane potential is established and maintained and how the membrane potential can change.
- 12-5 ■ Describe the events involved in the generation and propagation of an action potential and the factors involved in determining the speed of action potential propagation.
- 12-6 ■ Describe the structure of a synapse, and explain the mechanism involved in synaptic activity.
- 12-7 ■ Describe the major types of neurotransmitters and neuromodulators and discuss their effects on postsynaptic membranes.
- 12-8 ■ Discuss the interactions that enable information processing to occur in nervous tissue.

CLINICAL CASE

Did President Franklin D. Roosevelt Really Have Polio?

On August 10, 1921, at age 39, Franklin D. Roosevelt went to bed early feeling tired and complaining of back pain, fever, and chills. The next day, he experienced progressive weakness: first in one leg, then the other, in an ascending pattern. By August 12, both of his legs were paralyzed and numb, though he still felt pain when lightly touched. Over the following month, the signs and symptoms progressed to involve weakness and abnormal sensations of his upper extremities and his face, and he developed an inability to voluntarily urinate or defecate. His diagnosis of *poliomyelitis*, or *polio*, included him in one of the most feared epidemics of the early 20th century.

In the following months, Mr. Roosevelt gradually recovered from the severe weakness and pain. He also regained control of his bodily functions. His legs and buttocks, however, were permanently weakened.

Franklin Roosevelt went on to become the 32nd and longest-serving president of the United States. He assisted in founding the March of Dimes, an organization that contributed to the elimination of polio from most of the world. **But looking back on his clinical course, did President Franklin D. Roosevelt**

really have poliomyelitis, a viral disease of the motor neurons of the spinal cord? To find out, turn to the Clinical Case Wrap-Up at the end of the chapter.

12

An Introduction to the Nervous System and Nervous Tissue

The **nervous system** includes the various nervous organs throughout the body. These include the *brain*; the *spinal cord*; the *receptors* in complex sense organs, such as the eye and ear; and the *nerves* that link the nervous system with other body systems. Together these organs receive information from both external and internal stimuli, process that information, and send signals to initiate any necessary response. The organs of the nervous system are made up of **nervous tissue**, as well as supporting blood vessels and connective tissues.

The basic functional units of the nervous system are cells called *neurons* (NŪ-ronz), which are specialized for intercellular communication. Nervous tissue also includes supporting cells called *neuroglia* (nŪ-RŌG-lē-uh; *glia*, glue), or *glial cells*. Neuroglia have functions essential to the survival and functionality of neurons and to preserving the physical and biochemical structure of nervous tissue.

This chapter begins with a brief introduction to the nervous system as a whole, and then it explores nervous tissue structure and function and the principles governing neural activities. Later chapters then cover the various parts of the nervous system.

12-1 The nervous system has anatomical and functional divisions

Learning Outcome Describe the anatomical and functional divisions of the nervous system.

We can look at the nervous system from both anatomical and functional perspectives.

The Anatomical Divisions of the Nervous System

Viewed anatomically, the nervous system has two divisions: the *central nervous system* and the *peripheral nervous system* (**Figure 12-1**). The **central nervous system (CNS)** consists of the brain and spinal cord. These complex organs include not only nervous tissue, but also blood vessels and the various connective tissues that physically protect and support them.

What are the general functions of the CNS? It is responsible for integrating, processing, and coordinating sensory data and motor commands. Sensory data convey information about conditions inside or outside the body. Motor commands control or adjust peripheral organs, such as skeletal muscles. When someone stumbles, for example, the CNS integrates information about their balance and the position of their limbs and then coordinates their recovery by sending motor commands to appropriate skeletal muscles—all in a split second and without conscious effort. Additionally, the brain is the seat of higher functions, such as intelligence, memory, learning, and emotion.

The **peripheral nervous system (PNS)** includes all the nervous tissue outside the CNS and the ENS. There are two subdivisions of the PNS: the *somatic nervous system* and *autonomic nervous system*. The PNS delivers sensory information to the CNS and carries motor commands to peripheral tissues and systems, except those of the enteric nervous system. Bundles of axons, called *nerve fibers*, carry sensory information and motor commands in the PNS. Such bundles, with associated blood vessels and connective tissues, are called *peripheral nerves*, or simply **nerves**. Nerves connected to the brain are called **cranial nerves**, and those attached to the spinal cord are called **spinal nerves**.

Figure 12–1 An Overview of the Nervous System.

The Functional Divisions of the Nervous System

The CNS does not have separated functional divisions like the PNS, which is divided into afferent and efferent divisions (**Figure 12–1**). The **afferent division** (*afferens*, to bring toward) of the PNS brings sensory information to the CNS from receptors in peripheral tissues and organs. **Receptors** are sensory structures that either detect changes in the environment (internal or external) or respond to specific stimuli. Our receptors range from the slender cytoplasmic extensions of single cells to complex receptor organs, such as the eye and ear. Sensory receptors may be neurons or specialized cells of other tissues.

The **efferent division** (*effero*, to bring out) of the PNS carries motor commands from the CNS to muscles, glands, and adipose tissue. These target organs, which respond by *doing* something, are called **effectors**. The efferent division itself has two divisions, *somatic* and *autonomic*:

- The **somatic nervous system (SNS)** controls skeletal muscle contractions. *Voluntary* contractions are under conscious control. For example, a person exerts conscious

control over their arm as they raise a full glass of water to their lips. *Involuntary* contractions may be simple, automatic responses or complex movements, but they are controlled at the subconscious level, outside our awareness. For instance, if someone accidentally places their hand on a hot stove, they will withdraw it immediately, usually before they even notice any pain. This type of automatic response is called a **reflex**.

- The **autonomic nervous system (ANS)**, or *visceral motor system*, automatically regulates smooth muscle, cardiac muscle, glandular secretions, and adipose tissue at the subconscious level. The ANS includes a *parasympathetic division* and a *sympathetic division*, which commonly have antagonistic (opposite) effects. For example, parasympathetic activity slows the heart rate, whereas sympathetic activity accelerates the heart rate.

The autonomic nervous system also includes the *enteric nervous system* (ENS). The enteric nervous system is an extensive network of neurons and nerve networks in the walls of the digestive tract from the esophagus to the anus. Although

the sympathetic and parasympathetic divisions both influence ENS activities, the ENS initiates and coordinates many complex visceral reflexes locally and without instructions from the CNS. Altogether, the ENS has about 100 million neurons—at least as many as the spinal cord. It also uses the same neurotransmitters found in the brain. We discuss the role of the ENS in Chapter 24.

Now that you have an overview of the nervous system, let's turn our attention to neuron structures.

✓ Checkpoint

1. Describe the two anatomical divisions of the nervous system.
2. Describe the two functional divisions of the peripheral nervous system and cite their primary functions.
3. Identify the two components of the efferent division of the PNS and their effectors.
4. What would be the effect of damage to the afferent division of the PNS?

12 See the blue Answers tab at the back of the book.

12-2 Neurons are nerve cells specialized for intercellular communication

Learning Outcome Sketch and label the structure of a typical neuron, describe the functions of each component, and classify neurons based on their structure and function.

An understanding of neuron function requires knowing its structural components. After we describe the characteristics of a **neuron**, the basic functional unit of the nervous system, we examine the structure of a representative neuron and how it is specialized for intercellular communication. Then we consider the structural and functional classifications of neurons.

Functional Characteristics of Neurons

Neurons are generally long-lived and have a high metabolic rate. Like skeletal muscle cells, neurons have an excitable plasma membrane. The generation and propagation of action potentials place a large demand on a neuron's energy resources. Energy is also expended in synthesizing and secreting the chemical compounds necessary for sending information from neuron to neuron. Mitochondria in various parts of a neuron generate the energy needed by an active neuron.

Most neurons lack centrioles, organelles that help to organize the cytoskeleton and the microtubules that move chromosomes during mitosis. As a result, typical CNS neurons cannot divide. For this reason, they cannot be replaced if lost to injury or disease. Neural stem cells persist in the adult nervous system, but they are typically inactive except in the nose, where the regeneration of olfactory (smell) receptors maintains our

sense of smell, and in the *hippocampus*, a part of the brain involved in storing memories. Researchers are investigating the control mechanisms that trigger neural stem cell activity, with the goal of preventing or reversing neuron loss due to trauma, disease, or aging.

The Structure of Neurons

Neurons have a variety of shapes. **Figure 12-2** shows an example of the most common type of neuron in the central nervous system. Each such neuron has four general regions: a large *cell body*; several short, branched *dendrites*; a single, long *axon*; and terminal branches of the axon called *telodendria* (**Figure 12-2a**).

The Cell Body

The **cell body**, or *soma*, contains a large, round nucleus with a prominent nucleolus (**Figure 12-2b**). The cytoplasm surrounding the nucleus is the **perikaryon** (per-i-KAR-ē-on; *peri-*, around + *karyon*, nucleus). The cytoskeleton of the perikaryon contains **neurofilaments** and **neurotubules**, which are similar to the intermediate filaments and microtubules of other types of cells. Bundles of neurofilaments, called **neurofibrils**, extend into the dendrites and axon, providing internal support for them.

The perikaryon contains organelles that provide energy and synthesize organic materials, especially the chemical *neurotransmitters* that are important in cell-to-cell communication. The numerous mitochondria, free and fixed ribosomes, and membranes of rough endoplasmic reticulum (RER) give the perikaryon a grainy appearance. Mitochondria generate ATP to meet a neuron's energy needs. The ribosomes and RER synthesize proteins.

Some areas of the perikaryon contain clusters of RER and free ribosomes. These regions, which stain darkly with cresyl violet, a common histology dye, are called *Nissl bodies*. They were named after the German neurologist Franz Nissl, who first described them. Nissl bodies give a gray color to areas containing neuron cell bodies—the *gray matter* visible in gross dissection of the brain and spinal cord.

Dendrites, Axons, and Telodendria

A variable number of slender processes (extensions) known as **dendrites** extend and branch out from the cell body (**Figure 12-2a**). Dendrites play key roles in intercellular communication. Typical dendrites are highly branched, and some branches are studded with fine 0.5 to 1 μm projections called *dendritic spines*, which participate in synapses. In the CNS, a neuron receives information from other neurons primarily at the dendritic spines, which may represent 80–90% of the neuron's total surface area.

An **axon** is a long cytoplasmic process, up to a meter in length, which is capable of propagating an electrical impulse known as an *action potential*. The **axoplasm** (AK-sō-plazm), or cytoplasm of the axon, contains neurofibrils, neurotubules,

Figure 12-2 The Anatomy of a Typical Neuron.

The axon hillock lies between what two other general regions of a neuron?

12

small vesicles, lysosomes, mitochondria, and various enzymes. The **axolemma**, the plasma membrane of the axon, surrounds the axoplasm. In the CNS, the axolemma may be exposed to the interstitial fluid or, as we'll learn, it may be covered by the cellular processes of neuroglia. The base, or **initial segment**, of the axon in a typical neuron joins the cell body at a thickened region known as the **axon hillock** (Figure 12-2b).

An axon may branch along its length, producing side branches known as **collaterals**. Collaterals enable a single neuron to communicate with several other cells. The main axon trunk and any collaterals end in a series of fine extensions called **telodendria** (tel-ō-DEN-drē-uh; *telo-*, end + *dendron*, tree), or *terminal branches*. The telodendria, in turn, end at **axon terminals** (also called *synaptic terminals*), which play a communicating role with another cell. A *synapse* is where a neuron communicates with another cell, possibly another neuron (described in Section 12-6).

The movement of materials between the cell body and axon terminals is called **axonal (axoplasmic) transport**. These materials travel the length of the axon on neurotubules in the axoplasm, pulled along by protein "molecular motors," called *kinesin* and *dynein*, which require ATP. Some materials travel slowly, at rates of a few millimeters per day. This transport mechanism is known as the "slow stream." Some vesicles move much more rapidly, traveling in the "fast

stream" at a rate as high as 1000 mm (1 m) per day, but the average is around 300 mm per day.

Axonal transport occurs simultaneously in both directions. The flow of materials from the cell body to the axon terminal is *anterograde* (AN-ter-ō-grād; *antero-*, forward) *flow*, carried by kinesin. At the same time, other substances are transported from the axon terminal toward the cell body in *retrograde* (RET-rō-grād) *flow* (*retro*, backward), carried by dynein. If debris or unusual chemicals appear in the axon terminal, retrograde flow soon delivers them to the cell body. There they may then alter the activity of the cell by turning certain genes on or off.

Clinical Note Rabies

Rabies is an example of a clinical condition involving retrograde flow. When a bite from a rabid animal injects the rabies virus into peripheral tissues, the virus particles quickly enter axon terminals and peripheral axons. Retrograde flow then carries the virus into the CNS, with fatal results. Many toxins (including heavy metals), some pathogenic bacteria, and other viruses also bypass CNS defenses through axonal transport.

Figure 12-3 Structural Classifications of Neurons.

The Classification of Neurons

We can group neurons by structure or by function.

Structural Classification of Neurons

Neurons are classified as *anaxonic*, *bipolar*, *unipolar*, or *multipolar* based on the relationship of the dendrites to the cell body and the axon (**Figure 12-3**):

- **Anaxonic** (an-aks-ON-ik; *an-*, without) **neurons** are small and have numerous dendrites, but no obvious axons. Some do have axons, yet they are not readily visible, even when viewed with a microscope. Anaxonic neurons are in the brain and in special sense organs. Their functions are poorly understood.
- **Bipolar neurons** have two distinct processes—one dendrite (that branches extensively into dendritic branches at its distal tip) and one axon—with the cell body between the two. Bipolar neurons are rare. They occur in special sense organs, where they relay information about sight, smell, or hearing from receptor cells to other neurons. Bipolar neurons are relatively small: The largest measure less than 30 μm (0.03 mm) from end to end.
- In a **unipolar neuron**, or *pseudounipolar neuron*, the dendrites and axon are continuous—basically, fused—and

the cell body lies off to one side. In such a neuron, the initial segment lies where the dendrites converge. The rest of the process, which carries action potentials, is usually considered an axon. Most sensory neurons of the peripheral nervous system are unipolar. Their axons may extend a meter or more, ending at synapses in the central nervous system. The longest axons of unipolar neurons carry sensations from the tips of the toes to the spinal cord.

- **Multipolar neurons** have two or more dendrites and a single axon. They are the most common neurons in the CNS. All the motor neurons that control skeletal muscles, for example, are multipolar neurons. The longest axons of multipolar neurons carry motor commands from the spinal cord to small muscles that move the toes.

Functional Classification of Neurons

Alternatively, we can categorize neurons by function as (1) *sensory neurons*, (2) *motor neurons*, or (3) *interneurons*.

Sensory Neurons. **Sensory neurons**, or *afferent neurons*, form the afferent division of the PNS. The cell bodies of sensory neurons are located in peripheral *sensory ganglia*. (A **ganglion** is a collection of neuron cell bodies in the PNS.) Sensory neurons are unipolar neurons whose processes, known as

afferent fibers, extend between a sensory receptor and the CNS (they deliver information from sensory receptors to the spinal cord or brain). The human body's 10 million or so sensory neurons collect information about the external or internal environment. **Somatic sensory neurons** monitor the outside world and our position within it. **Visceral sensory neurons** monitor internal conditions and the status of other organ systems (**Figure 12-1**).

Sensory receptors are either the processes of specialized sensory neurons or cells monitored by sensory neurons. We can broadly categorize these receptors into three groups:

- **Interoceptors** (*intero-*, inside) monitor the digestive, respiratory, cardiovascular, urinary, and reproductive systems and provide sensations of distension (stretch), deep pressure, and pain.
- **Exteroceptors** (*extero-*, outside) provide information about the external environment in the form of touch, temperature, or pressure sensations and the more complex senses of taste, smell, sight, equilibrium (balance), and hearing.
- **Proprioceptors** (*prō-prē-ō-SEP-terz*) monitor the position and movement of skeletal muscles and joints.

Motor Neurons. **Motor neurons**, or *efferent neurons*, form the efferent division of the PNS. The half a million motor neurons carry instructions from the CNS to peripheral effectors in a peripheral tissue, organ, or organ system. Axons of these neurons that travel away from the CNS are called **efferent fibers**. As noted earlier, the two major efferent systems are the somatic nervous system (SNS) and the autonomic (visceral) nervous system (ANS) (**Figure 12-1**).

The somatic nervous system includes all the **somatic motor neurons** that innervate skeletal muscles. You have conscious control over the activity of the SNS. The cell body of a somatic motor neuron lies in the CNS, and its axon runs within a peripheral nerve to innervate skeletal muscle fibers at neuromuscular junctions.

You do not have conscious control over the activities of the ANS. **Visceral motor neurons** innervate all peripheral effectors other than skeletal muscles—that is, smooth muscle, cardiac muscle, glands, and adipose tissue throughout the body. The axons of visceral motor neurons in the CNS innervate a second set of visceral motor neurons in peripheral *autonomic ganglia*. The neurons whose cell bodies are in those ganglia innervate and control peripheral effectors.

Tips

To distinguish between *afferent* and *efferent*, think of the **SAME** principle: **S** is for **s**ensory, **A** is for **a**fferent, **M** is for **m**otor, and **E** is for **e**fferent. This way, you associate the **S** and **A** together and the **M** and **E** together.

To pass from the CNS to a visceral effector such as a smooth muscle cell, a signal must travel along one axon, be relayed across a synapse, and then travel along a second axon to its destination. The axons extending from the CNS to an autonomic ganglion are called *preganglionic fibers*, and axons connecting the ganglion cells with the peripheral effectors are known as *postganglionic fibers*.

Interneurons. **Interneurons** are located between sensory and motor neurons. The 20 billion or so interneurons (*association neurons*) outnumber all other types of neurons combined. Most are located within the brain and spinal cord, but some are in autonomic ganglia. The main function of interneurons is integration—they distribute sensory information and coordinate motor activity. The more complex the response to a given stimulus, the more interneurons are involved. Interneurons also play a part in all higher functions, such as memory, planning, and learning.

Now, we turn our attention to the neuroglia, cells that support and protect the neurons.

Checkpoint

5. Name the structural components of a typical neuron.
6. Classify neurons according to their structure.
7. Classify neurons according to their function.
8. Are unipolar neurons in a tissue sample more likely to function as sensory neurons or motor neurons?

See the blue Answers tab at the back of the book.

12-3 CNS and PNS neuroglia support and protect neurons

Learning Outcome Describe the locations and functions of the various types of neuroglia.

Neuroglia separate and protect neurons, provide a supportive framework for nervous tissue, act as phagocytes, and help regulate the composition of the interstitial fluid. Neuroglia are abundant and diverse; in fact, they make up about half the volume of the nervous system, far outnumbering the neurons.

The organization of nervous tissue in the CNS differs from that in the PNS, primarily because the CNS has a greater variety of neuroglia. Histological descriptions have been available for quite some time, but the technical problems involved in isolating and manipulating individual glial cells have provided obstacles to understanding their functions. **Figure 12-4** summarizes what we know about the major neuroglial populations in the CNS and PNS.

Neuroglia of the Central Nervous System

The central nervous system has four types of neuroglia: (1) *astrocytes*, (2) *ependymal cells*, (3) *oligodendrocytes*, and (4) *microglia* (**Figure 12-4**).

Figure 12-4 An Introduction to Neuroglia.

Which neuroglia myelinate CNS axons and which neuroglia myelinate PNS axons?

Astrocytes

Astrocytes (AS-trō-sīts; *astro-*, star + *-cyte*, cell) are the largest and most numerous neuroglia in the CNS (**Figure 12-5**). The star-shaped astrocytes (hence their name) have many slender cytoplasmic processes that end in expanded “feet.” Astrocytes are packed with microfilaments that extend across the breadth of the cell and its processes. These cells are connected to each other by gap junctions.

Astrocytes have a variety of functions:

- **Maintaining the Blood-Brain Barrier (BBB).** The **blood-brain barrier (BBB)** is a filtering mechanism of the capillaries that carry blood to the brain and spinal cord. This selectively permeable barrier allows the passage of some substances but limits the passage of others. Astrocytes create this blood-brain barrier, isolating the CNS from the general circulation. The expanded “feet” of astrocytes form a complete blanket around the capillaries, interrupted only where

other neuroglia come in contact with the capillary walls. Astrocytes secrete chemicals that are responsible for maintaining the special permeability characteristics of the capillary endothelial cells. (We discuss the blood-brain barrier further in Chapter 14.)

- **Creating a Three-Dimensional Framework for the CNS.** The extensive cytoskeleton of astrocytes helps provide a structural framework for the neurons of the brain and spinal cord.
- **Repairing Damaged Nervous Tissue.** In the CNS, damaged nervous tissue seldom regains normal function. However, astrocytes that move into an injury site can make structural repairs that stabilize the tissue and prevent further injury. We discuss neural damage and repair later in this section.
- **Guiding Neuron Development.** Astrocytes in the embryonic brain appear to be involved in directing both the growth and interconnection of developing neurons.

Figure 12-5 Neuroglia in the CNS.

A diagram of nervous tissue in the CNS showing relationships between neuroglia and neurons

- **Controlling the Interstitial Environment.** Astrocytes appear to adjust the composition of interstitial fluid by several means: (1) regulating the concentration of sodium ions, potassium ions, and carbon dioxide; (2) providing a “rapid-transit system” for transporting nutrients, ions, and dissolved gases between capillaries and neurons; (3) controlling the volume of blood flow through the capillaries; (4) absorbing and recycling some neurotransmitters; and (5) releasing chemicals that enhance or suppress communication across axon terminals.

Ependymal Cells

A fluid-filled central passageway extends along the longitudinal axis of the spinal cord and brain. Protective *cerebrospinal fluid* (CSF) fills this passageway and also surrounds the brain and spinal cord. In the spinal cord, this passageway is called the *central canal* (Figure 12-5). In several regions of the brain, the passageway forms enlarged chambers called *ventricles*.

Ependymal (eh-PEN-di-mul) **cells** line the central canal and ventricles, where they form a simple cuboidal to ciliated columnar epithelium. Ependymal cells assist in producing and monitoring CSF. In addition, the cilia of the ependymal cells help to circulate CSF in the third ventricle of the brain. The role of ependymal cells in CSF production is discussed in Chapter 14.

During early embryonic development, stem cells lining the central canal and ventricles divide to give rise to neurons and all CNS neuroglia other than microglia. In adults, the ependymal epithelium appears to contain neural stem cells that can divide to produce additional neurons.

Oligodendrocytes and Myelination

Like astrocytes, **oligodendrocytes** (ol-i-gō-DEN-drō-sīts; *oligo-*, few) have slender cytoplasmic extensions, but the cell bodies

of oligodendrocytes are smaller, with fewer processes, than astrocytes (Figure 12-5). The processes of oligodendrocytes generally are in contact with the exposed surfaces of neurons. The functions of processes ending at the neuron cell body are an area of active research. Much more is known about the processes that end on the surfaces of axons. Many axons in the CNS are completely sheathed in these processes, which insulate them from contact with the extracellular fluid.

During its maturation, the plasma membrane near the tip of each process of an oligodendrocyte expands to form a relatively enormous pad, and the cytoplasm there becomes very thin. This flattened “pancake” wraps around the axolemma, forming concentric layers of plasma membrane (Figure 12-5). This membranous wrapping, called **myelin** (MĪ-e-lin), serves as electrical insulation and increases the speed at which an action potential travels along the axon. (We describe this mechanism in Section 12-5.)

Many oligodendrocytes cooperate in forming a **myelin sheath** along the length of an axon. Such an axon is said to be **myelinated**. Each oligodendrocyte myelinates segments of several axons. The fairly large areas of the axon that are wrapped in myelin are called **internodes** (*inter*, between). Internodes are typically 1–2 mm in length. The small gaps of a few micrometers that separate adjacent internodes are called **nodes**, or *nodes of Ranvier* (rahn-vē-Ā). An axon’s collateral branches originate at nodes.

In dissection, myelinated axons appear glossy white, primarily because of the lipids in the myelin. As a result, regions dominated by myelinated axons are known as the **white matter** of the CNS. Not all axons in the CNS are myelinated, however. **Unmyelinated axons** are not completely covered by oligodendrocytes. Such axons are common where short axons and collaterals form synapses with densely packed neuron cell bodies. Areas containing neuron cell bodies, dendrites, and unmyelinated axons have a dusky gray color and make up the **gray matter** of the CNS (Figure 12-5).

In summary, oligodendrocytes play an important role in structural organization by tying clusters of axons together. They also improve the functioning of neurons by wrapping axons within a myelin sheath.

Tips

The color of CNS tissue is related to its structure and function. **Gray** matter has a **great** concentration of neuron cell bodies and is a region of **integration**. **White** matter has a **whole** lot of myelinated axons and **whisks** nerve impulses.

Microglia

The least numerous and smallest neuroglia in the CNS are phagocytic cells called **microglia** (mĪ-KRŌG-lē-uh). Their slender processes have many fine branches (Figure 12-5).

Clinical Note CNS Tumors

Tumors of the brain, spinal cord, and associated membranes result in approximately 90,000 deaths in the United States each year. *Primary CNS tumors* are tumors that originate in the central nervous system. *Secondary CNS tumors* arise from the metastasis (spread) of cancer cells that originate elsewhere. About 75% of CNS tumors are primary tumors. In adults, primary CNS tumors result from the divisions of abnormal neuroglia rather than from the divisions of abnormal neurons, because typical neurons in adults cannot divide. However, through the divisions of stem cells, neurons increase in number until children reach age 4. For this reason, primary CNS tumors involving abnormal neurons can occur in young children.

These cells can migrate through nervous tissue, acting as a wandering janitorial service and police force by engulfing cellular debris, wastes, and pathogens.

Microglia appear early in embryonic development, originating from mesodermal stem cells related to stem cells that produce monocytes and macrophages. Microglia migrate into the CNS as the nervous system forms.

Neuroglia of the Peripheral Nervous System

Recall that the cell bodies of neurons in the PNS are clustered in masses called ganglia. The processes of neuroglia completely insulate neuronal cell bodies and most axons in the PNS from their surroundings. The two types of neuroglia in the PNS are *satellite cells* and *Schwann cells* (Figure 12-4).

Satellite cells surround neuron cell bodies in ganglia. They regulate the interstitial fluid around the neurons, much as astrocytes do in the CNS.

Schwann cells, or *neurolemmocytes*, form either a thick, myelin sheath or indented folds of plasma membrane around

peripheral axons in all parts of the peripheral nervous system. Wherever a Schwann cell covers an axon, the outer surface of the Schwann cell is called the **neurolemma**. It shields the axon from contact with interstitial fluids. Gaps between Schwann cells are called *nodes*.

A myelinating Schwann cell myelinates only one axon (Figure 12-6a), whereas one oligodendrocyte in the CNS may myelinate several axons (review Figure 12-5). Non-myelinating Schwann cells can *enclose* segments of several unmyelinated axons. A series of Schwann cells is required to enclose an axon along its entire length (Figure 12-6b). Stages in the formation of a myelin sheath by a myelinating Schwann cell around the axon of a peripheral neuron are shown in Figure 12-6c.

Neural Responses to Injuries

What happens when a neuron is injured? It responds to injury in a very limited way, although in general more repair is possible in PNS neurons than in those of the CNS.

12

Clinical Note Demyelination

Demyelination is the progressive destruction of myelin sheaths, both in the CNS and in the PNS. The result is a loss of sensation and motor control that leaves affected regions numb and paralyzed. Many unrelated conditions that result in the destruction of myelin can cause symptoms of demyelination.

Chronic exposure to **heavy-metal ions**, such as arsenic, lead, or mercury, can cause heavy-metal poisoning, leading to neuroglial damage and demyelination.

Diphtheria (dif-THER-ē-uh) is a bacterial disease that damages Schwann cells and destroys myelin sheaths in the PNS. The resulting demyelination leads to sensory and motor problems that can ultimately produce a fatal paralysis. Due to an effective vaccine (the “D” in the “DPT” immunization record), cases are relatively rare.

Multiple sclerosis (skler-ō-sis; *sklerosis*, hardness), or **MS**, is the most common demyelinating disease. It is characterized by recurrent demyelinating episodes that affect axons in the optic nerve, brain, and spinal cord. Although the precise cause of MS is yet to be discovered, myelin becomes the target of an autoimmune reaction. Inflammation occurs at multiple sites where white matter is located. Healing produces multiple scars, which account for the name of the disease. Common signs include partial loss of vision and problems with speech, balance, and general motor coordination, including bowel and urinary bladder control. The course of MS varies from person to person. Most often, the individual experiences a cycle of attacks and recovery.

The first attack typically occurs in people 20–40 years old. The incidence in females is twice that of males. Curiously, MS is more common in cold climates and in persons of northern European descent, regardless of where they live. Although no cure currently exists, corticosteroid or interferon injections have slowed the progression of the disease in some patients. Multiple sclerosis is the most common disabling neurological disease of young adults.

Figure 12-6 Schwann Cells, Peripheral Axons, and Formation of the Myelin Sheath in the PNS.

a A myelinated axon, showing the organization of Schwann cells along the length of the axon.

b The enclosing of a group of unmyelinated axons by a single Schwann cell. A series of Schwann cells is required to cover the axons along their entire length.

c Stages in the formation of a myelin sheath by a single Schwann cell along a portion of a single axon.

After an injury, the Nissl bodies in the cell body disperse and the nucleus moves away from its centralized location as the cell increases its rate of protein synthesis. If the neuron recovers and regains function, it will regain its normal appearance.

The key to recovery appears to be events in the axon. If, for example, the pressure applied during a crushing injury produces a local decrease in blood flow and oxygen, the affected axolemma becomes unexcitable. If the pressure is alleviated after an hour or two, the neuron will recover within a few weeks. More severe or prolonged pressure produces effects similar to those caused by cutting the axon.

In the PNS, Schwann cells play a part in repairing damaged nerves. In the process known as **Wallerian** (vah-LEHR-ē-an) **degeneration**, the axon distal to the injury site degenerates, and macrophages migrate into the area to clean up the debris (**Figure 12-7**). The Schwann cells do not degenerate. Instead, they proliferate and form a solid cellular cord that follows the path of the original axon. As the neuron recovers, its axon grows into the site of injury, and the Schwann cells wrap around the axon.

If the axon grows alongside the appropriate cord of Schwann cells, it may eventually reestablish its normal synaptic contacts. However, if it stops growing or wanders off in some new direction, normal function will not return. The growing axon is most likely to arrive at its appropriate destination if the cut edges of the original nerve bundle remain in contact.

Limited regeneration can occur in the CNS, but the situation is more complicated because (1) many more axons are likely to be involved, (2) astrocytes produce scar tissue that can prevent axon growth across the damaged area, and (3) astrocytes release chemicals that block the regrowth of axons.

Checkpoint

9. List the neuroglia of the central nervous system.
10. Identify the neuroglia of the peripheral nervous system.
11. Which type of neuroglia would increase in number in the brain tissue of a person with a CNS infection?

See the blue Answers tab at the back of the book.

Figure 12-7 Peripheral Nerve Regeneration after Injury.

12-4 The membrane potential of a neuron is determined by differences in ion concentrations and membrane permeability

Learning Outcome Explain how the resting membrane potential is established and maintained and how the membrane potential can change.

In Chapter 3, we introduced the concepts of the *membrane potential* and the resting membrane potential, two characteristic physiological features of all cells. In this discussion, we focus on the membranes of neurons, but many of the principles discussed apply to other types of cells as well.

All living cells have a membrane potential that varies from moment to moment depending on the activities of the cell. The *resting membrane potential* is the membrane potential of an unstimulated, resting cell. All neural activities begin with a change in the resting membrane potential of a neuron. A typical stimulus produces a temporary, localized change in the resting membrane potential. The effect, which decreases with distance from the stimulus, is called a *graded potential*. If the graded potential is large enough, it triggers an *action potential* in the membrane of the axon, a process that we cover in the next section. Here we look at the important membrane processes of the resting membrane potential and graded potentials.

The Resting Membrane Potential

Chapter 3 introduced three important concepts regarding the membrane potential:

- *The extracellular fluid (ECF) and intracellular fluid (cytosol) differ greatly in ionic composition.* The extracellular fluid contains high concentrations of sodium ions (Na^+) and chloride ions (Cl^-), whereas the cytosol contains high concentrations of potassium ions (K^+) and negatively charged proteins.
- *Cells have selectively permeable membranes.* If the plasma membrane were freely permeable, diffusion would continue until all the ions were evenly distributed across the membrane and a state of equilibrium existed. Such an even distribution does not occur, because cells have selectively permeable membranes. Ions cannot freely cross the lipid portions of the plasma membrane. They can enter or leave the cell only through ion channels within large proteins that are anchored in specific areas of the plasma membrane. Many kinds of membrane ion channels exist, each with its own properties. At the **resting membrane potential**, or membrane potential of an undisturbed cell, ions move through *leak channels*—membrane channels that are always open. Active transport mechanisms, such as the sodium–potassium exchange pump, also move specific ions into or out of the cell.
- *Membrane permeability varies by ion.* The cell's passive and active transport mechanisms do not ensure an equal distribution of charges across its plasma membrane,

because membrane permeability varies by ion. For example, it is easier for K^+ to diffuse out of the cell through a potassium leak channel than it is for Na^+ to enter the cell through a sodium leak channel. Additionally, negatively charged proteins inside the cell are too large to cross the membrane. As a result, the membrane's inner surface has an excess of negative charges with respect to the outer surface.

Both passive and active forces act across the plasma membrane to determine the membrane potential at any moment. **Spotlight Figure 12-8** shows the processes that lead to the normal resting membrane potential.

Passive Processes Acting across the Plasma Membrane: The Electrochemical Gradient

The passive processes acting across the plasma membrane involve both chemical and electrical gradients (**Spotlight Figure 12-8**). Positive and negative charges attract one another. If nothing separates them, oppositely charged ions will move together and eliminate the potential difference between them. A movement of charges to eliminate a potential difference is called a **current**. If a barrier (such as a plasma membrane) separates the oppositely charged ions, the amount of current depends on how easily the ions can cross the membrane. The **resistance** of the membrane is a measure of how much the membrane restricts ion movement. If the resistance is high, the current is very small, because few ions can cross the membrane. If the resistance is low, the current is very large, because ions flood across the membrane. The resistance of a plasma membrane can change as ion channels open or close. The changes result in currents carrying ions into or out of the cytosol.

Electrical gradients can either reinforce or oppose the chemical gradient for each ion. The **electrochemical gradient** for a specific ion is the sum of the chemical and electrical forces acting on that ion across the plasma membrane. The electrochemical gradients for K^+ and Na^+ are the primary factors affecting the resting membrane potential of most cells, including neurons. Let's consider the forces acting on each ion independently.

The intracellular concentration of potassium ions is relatively high, whereas the extracellular concentration is very low. Therefore, the chemical gradient for potassium ions tends to drive them out of the cell, as indicated by the thicker orange arrow in **Figure 12-9a**. However, the electrical gradient opposes this movement, because potassium ions inside and outside the cell are attracted to the negative charges on the inside of the plasma membrane and repelled by the positive charges on the outside of the plasma membrane. The white arrow in **Figure 12-9a** indicates the size and direction of this electrical gradient. The chemical gradient is strong enough to overpower the electrical gradient, but the electrical gradient weakens the force driving K^+ out of the cell. The thinner orange arrow represents the net driving force of the potassium ion electrochemical gradient.

All living cells have a membrane potential that varies from moment to moment depending on the activities of the cell. In an unstimulated, resting cell, the *potential difference* between positive and negative ions on either side of the membrane is called the **resting membrane potential**. Passive and active forces determine the resting membrane potential.

Passive Chemical Gradients

The intracellular concentration of potassium ions (K^+) is relatively high, so these ions tend to move out of the cell through potassium leak channels. Similarly, the extracellular concentration of sodium ions (Na^+) is relatively high, so these ions move into the cell through sodium leak channels. Each ion's movement is driven by a concentration gradient, or **chemical gradient**.

Active Na^+/K^+ Pumps

Sodium-potassium (Na^+/K^+) exchange pumps maintain the concentration gradients of sodium and potassium ions across the plasma membrane.

Passive Electrical Gradients

Potassium ions leave the cytosol more rapidly than sodium ions enter because the plasma membrane is much more permeable to potassium than to sodium. As a result, there are more positive charges outside the plasma membrane. Negatively charged protein molecules within the cytosol cannot cross the plasma membrane, so there are more negative charges on the cytosol side of the plasma membrane. This results in an **electrical gradient** across the plasma membrane.

Resting Membrane Potential

Whenever positive and negative ions are held apart, a potential difference arises. We measure the size of that potential difference in millivolts (mV). The resting membrane potential for most neurons is about -70 mV. The minus sign shows that the inner surface of the plasma membrane is negatively charged with respect to the exterior.

Figure 12-9 Electrochemical Gradients for Potassium and Sodium Ions.

If the plasma membrane were freely permeable to K^+ but impermeable to other positively charged ions, potassium ions would continue to leave the cell until the electrical gradient (opposing the exit of K^+ from the cell) was as strong as the chemical gradient (driving K^+ out of the cell). The membrane potential at which there is no net movement of a particular ion across the plasma membrane is called the **equilibrium potential**

for that ion. For potassium ions, this equilibrium occurs at a membrane potential of about -90 mV, as illustrated in **Figure 12-9b**. The resting membrane potential of neurons is typically -70 mV, a value close to the equilibrium potential for K^+ . The difference is due primarily to Na^+ leaking continuously into the cell. The equilibrium potential indicates an ion's contribution to the resting membrane potential.

Tips

To remember the relative distribution of ions across the resting cell's plasma membrane, associate **N**egative with the **i**nside and **p**Ositive with the **O**utside.

The sodium ion concentration is relatively high in the extracellular fluid, but extremely low inside the cell. As a result, there is a strong chemical gradient driving Na^+ into the cell (the thinner purple arrow in **Figure 12-9c**). In addition, the extracellular sodium ions are attracted by the excess of negative charges on the inner surface of the plasma membrane. The white arrow in **Figure 12-9c** shows the relative size and direction of this electrical gradient. Both electrical forces and chemical forces drive Na^+ into the cell, and the larger lavender arrow represents the net driving force.

If the plasma membrane were freely permeable to Na^+ , these ions would continue to cross it until the interior of the cell contained enough excess positive charges to reverse the electrical gradient. In other words, ion movement would continue until the interior developed such a strongly positive charge that repulsion between the positive charges would prevent any further net movement of Na^+ into the cell. The equilibrium potential for Na^+ is approximately +66 mV, as shown in **Figure 12-9d**. The resting membrane potential is nowhere near that value because the resting membrane permeability to Na^+ is very low, and because ion pumps in the plasma membrane eject sodium ions as fast as they cross the membrane.

An electrochemical gradient is a form of *potential energy*. Potential energy is stored energy—the energy of position, as exists in a stretched spring, a charged battery, or water behind a dam. Without a plasma membrane, diffusion would eliminate all electrochemical gradients. In effect, the plasma membrane acts like a dam across a river. Without the dam, water would simply respond to gravity and flow downstream, gradually losing energy. With the dam in place, even a small opening releases water under tremendous pressure. Similarly, any stimulus that increases the permeability of the plasma membrane to sodium or potassium ions produces sudden and dramatic ion movement. For example, a stimulus that opens sodium ion channels triggers a rush of Na^+ into the cell. Note that the nature of the stimulus does not determine the amount of ion movement: If the stimulus opens the door, the electrochemical gradient does the rest.

Active Processes across the Membrane: The Sodium–Potassium Exchange Pump

We can compare a cell to a leaky fishing boat loaded with tiny fish floating in the sea. The hull represents the plasma membrane; the fish, K^+ ; and the ocean water, Na^+ . As the boat pitches and rolls, water comes in through the cracks, and fish swim out. If the boat is to stay afloat and the catch kept, we must pump the water out and recapture the lost fish.

Table 12-1 The Resting Membrane Potential

- Because the plasma membrane is highly permeable to potassium ions, the resting membrane potential of approximately –70 mV is close to –90 mV, the equilibrium potential for K^+ .
- The electrochemical gradient for sodium ions is very large, but the membrane's permeability to these ions is very low. Consequently, Na^+ has only a small effect on the normal resting membrane potential, making it just slightly less negative than the equilibrium potential for K^+ .
- The sodium–potassium exchange pump ejects 3Na^+ ions from the cell for every 2K^+ ions that it brings into the cell. It serves to stabilize the resting membrane potential when the ratio of Na^+ entry to K^+ loss through passive channels is 3:2.
- At the normal resting membrane potential, these passive and active mechanisms are in balance. The resting membrane potential varies widely with the type of cell. A typical neuron has a resting membrane potential of approximately –70 mV.

Similarly, at the normal resting membrane potential, the cell must bail out sodium ions that leak in and recapture potassium ions that leak out. The “bailing” takes place through the activity of the sodium–potassium exchange pump powered by ATP (**Spotlight Figure 12-8**). This pump exchanges three intracellular sodium ions for two extracellular potassium ions. At the normal resting membrane potential, this pump ejects sodium ions as quickly as they enter the cell. In this way, the activity of the exchange pump exactly balances the passive forces of diffusion, and the resting membrane potential remains stable because the ionic concentration gradients are maintained.

Table 12-1 summarizes the important features that lead to the resting membrane potential.

Changes in the Resting Membrane Potential: Membrane Channels

As noted previously, the resting membrane potential is the membrane potential of an “undisturbed” cell. Recall that it exists because (1) the cytosol differs from extracellular fluid in chemical and ionic composition, and (2) the plasma membrane is selectively permeable. Yet cells are dynamic structures that continually modify their activities, either in response to external stimuli or to perform specific functions. The membrane potential is equally dynamic, rising or falling in response to temporary changes in membrane permeability. Those changes result from the opening or closing of specific membrane ion channels.

Membrane channels control the movement of ions across the plasma membrane. We focus on the permeability of the membrane to sodium and potassium ions. These ions are the primary determinants of the membrane potential of many cell types, including neurons. Sodium and potassium ion channels are either passive or active.

Passive Ion Channels

Passive ion channels, called **leak channels**, are always open. However, their permeability can vary from moment to moment as the proteins that make up the channel change shape in

response to local conditions. As noted earlier, leak channels are important in establishing the normal resting membrane potential of the cell (**Spotlight Figure 12-8**).

Active Ion Channels

Plasma membranes also contain active channels, called **gated ion channels**, that open or close in response to specific stimuli. Three classes of gated channels exist: chemically gated, or ligand-gated channels; voltage-gated channels; and mechanically gated channels.

- **Chemically gated ion channels, or ligand-gated ion channels**, open or close when they bind specific chemicals, or ligands (**Figure 12-10a**). For example, the receptors that bind acetylcholine (ACh) at the neuromuscular junction are chemically gated ion channels. Chemically gated ion channels are most abundant on the dendrites and cell body of a neuron, the areas where most synaptic communication occurs.
- **Voltage-gated ion channels** open or close in response to changes in the membrane potential. They are characteristic of areas of *excitable cell membrane*, a membrane capable

Figure 12-10 Types of Gated Ion Channels.

of generating and propagating an action potential. Examples of excitable membranes are the axons of unipolar and multipolar neurons, and the sarcolemma (including T tubules) of skeletal muscle fibers and cardiac muscle cells. The most important voltage-gated ion channels, for our purposes, are voltage-gated sodium ion channels, potassium ion channels, and calcium ion channels. These sodium ion channels have two gates that function independently: an *activation gate* that opens on stimulation, letting sodium ions into the cell, and an *inactivation gate* that closes to stop the entry of sodium ions (**Figure 12-10b**). Therefore, each voltage-gated ion channel can be in one of three states: (1) closed but capable of opening, (2) open (**activated**), or (3) closed and incapable of opening (**inactivated**).

- **Mechanically gated ion channels** open or close in response to physical distortion of the membrane surface, such as when pressure is applied due to the touch of a hand (**Figure 12-10c**). Such channels are important in sensory receptors that respond to touch, pressure, or vibration. We discuss these receptors in more detail in Chapter 15.

The fact that the distribution of membrane channels varies from one region of the plasma membrane to another affects how and where a cell responds to specific stimuli. For example, in a neuron, chemically gated ion channels are located on the cell body and dendrites. Voltage-gated Na^+ and K^+ channels are found along the axon. Additionally, voltage-gated Ca^{2+} channels occur at axon terminals. Later sections will show how these differences in distribution affect the way that neurons function.

At the resting membrane potential, most gated channels are closed. When gated channels open, the rate of ion movement across the plasma membrane increases, changing the membrane potential. Let's explore more about how this works.

Graded Potentials

Any stimulus that opens a gated channel produces a graded potential. **Graded potentials**, or *local potentials*, are changes in the membrane potential that cannot spread far from the site of stimulation.

Figure 12-11 shows what happens when the plasma membrane of a resting cell is exposed to a chemical that opens chemically gated sodium ion channels:

- 1 Sodium ions enter the cell and are attracted to the negative charges along the inner surface of the plasma membrane. As these additional positive charges spread out, the membrane potential shifts toward 0 mV. Any shift from the resting membrane potential toward a less negative potential is called a **depolarization**. Note that this term applies to both changes in potential from -70 mV to lesser negative values (-65 mV , -45 mV , -10 mV), as well as to membrane potentials above 0 mV ($+10\text{ mV}$, $+30\text{ mV}$). In all these changes, the membrane potential becomes more positive.

- 2 As the plasma membrane depolarizes, sodium ions are released from its outer surface. These ions, along with other extracellular sodium ions, then move toward the open channels, replacing ions that have already entered the cell. This movement of positive charges parallel to the inner and outer surfaces of a membrane that spreads the depolarization is called a **local current**.

In a graded potential, the degree of depolarization decreases with distance away from the stimulation site; in other words, the local current dissipates. Why? Depolarization lessens with distance because the cytosol offers considerable resistance to ion movement, and because some of the sodium ions entering the cell then move back out across the membrane through sodium leak channels. At some distance from the entry point, the effects on the membrane potential are undetectable.

The maximum change in the membrane potential is proportional to the size of the stimulus, which determines the number of open sodium ion channels. The more open channels, the more sodium ions enter the cell, the greater the membrane area affected, and the greater the degree of depolarization.

When the chemical stimulus is removed and normal membrane permeability is restored, the membrane potential soon returns to the resting level. The process of restoring the normal resting membrane potential after depolarization is called **repolarization** (**Figure 12-12**). Repolarization typically involves a combination of ion movement through membrane channels and the activities of ion pumps, especially the sodium–potassium exchange pump.

However, if a gated potassium ion channel opens in response to a stimulus, the opposite effect occurs. The rate of K^+ outflow increases, and the interior of the cell loses positive ions. In other words, the inside of the cell becomes more negative. The loss of positive ions produces **hyperpolarization**, an increase in the negativity of the resting membrane potential, for example, from -70 mV to perhaps -80 mV or more (**Figure 12-12**). Again, a local current distributes the effect to adjacent portions of the plasma membrane, and the effect decreases with distance from the open channels. **Table 12-2** summarizes the basic characteristics of graded potentials.

Table 12-2 Graded Potentials

Graded potentials, whether depolarizing or hyperpolarizing, share four basic characteristics:

- The membrane potential is most changed at the site of stimulation, and the effect decreases with distance.
- The effect spreads passively, due to local currents.
- The graded change in membrane potential may involve either depolarization or hyperpolarization. The properties and distribution of the membrane channels involved determine the nature of the change. For example, in a resting membrane, the opening of sodium ion channels causes depolarization, whereas the opening of potassium ion channels causes hyperpolarization. That is, the change in membrane potential reflects whether positive charges enter or leave the cell.
- The stronger the stimulus, the greater the change in the membrane potential and the larger the area affected.

Figure 12–11 Graded Potentials. The depolarization radiates in all directions away from the source of stimulation. For clarity, only gated ion channels are shown. Leak channels are present but are not responsible for producing graded potentials. Color changes in the plasma membrane indicate that the resting membrane potential has been disturbed and that the membrane potential is no longer -70 mV .

Resting State

2

Graded Potential

Spread of sodium ions along inner surface produces a local current that depolarizes adjacent portions of the plasma membrane

Graded potentials occur in the membranes of many types of cells—not just nerve and muscle cells, but epithelial cells, gland cells, adipocytes, and a variety of sensory receptors. Graded potentials often trigger specific cell functions. For example, a graded potential at the surface of a gland cell may

trigger the exocytosis of secretory vesicles. Similarly, at a neuromuscular junction, the neurotransmitter ACh may stimulate the depolarization of the motor end plate by a graded potential, which in turn may trigger an action potential in adjacent portions of the sarcolemma. The motor end plate supports

Figure 12–12 Depolarization, Repolarization, and Hyperpolarization.

graded potentials, but the rest of the sarcolemma consists of excitable membrane. These areas of membrane are different because they contain voltage-gated ion channels.

Let's look at how graded potentials can lead to action potentials in a neuron. If a graded potential causes hyperpolarization, an action potential becomes less likely, but if the graded potential causes depolarization, an action potential becomes more likely to occur.

Checkpoint

12. Define resting membrane potential.
13. What effect would a chemical that blocks the voltage-gated sodium ion channels in the plasma membrane of a neuron have on its ability to depolarize?
14. What effect would a decrease in the concentration of extracellular potassium ions have on the membrane potential of a neuron?

See the blue Answers tab at the back of the book.

12-5 An action potential is an all-or-none electrical event used for long-distance communication

Learning Outcome Describe the events involved in the generation and propagation of an action potential and the factors involved in determining the speed of action potential propagation.

Action potentials, also known as *nerve impulses*, are changes in the membrane potential that, once initiated, affect an entire excitable membrane. That is, action potentials are not graded potentials. An action potential is *propagated* (spread) along the surface of an axon and does not diminish as it moves away from its source. This impulse travels along the axon to the axon terminals.

We now take a closer look at the nature of action potentials and how they are generated and propagated. Generation and propagation are closely related concepts, in terms of both time and space: An action potential must be generated at one site before it can be propagated away from that site.

Threshold and the All-or-None Principle

A graded potential must depolarize the axolemma to a particular level to stimulate an action potential. The membrane potential at which an action potential begins is called the **threshold**. Threshold for an axon is typically between -60mV and -55mV , corresponding to a depolarization of 10 to 15 mV. A stimulus that shifts the resting membrane potential from -70mV to -62mV will not produce an action potential, only a graded depolarization. When such a stimulus is removed, the membrane potential returns to the resting level. Local currents resulting from the graded depolarization of the axon hillock cause the depolarization of the initial segment of the axon.

The initial depolarization acts like flipping a switch. If slight pressure is applied, nothing happens. The switch only flips if a certain minimum pressure is applied. Once the pressure on the switch reaches this threshold, the switch will flip. Once flipped, it no longer matters whether the pressure was gradually applied or suddenly applied. The point is that enough pressure, or threshold stimulus, was applied to flip the switch.

In the case of an axon or another area of excitable membrane, a graded depolarization is similar to the pressure on the switch, and the action potential is like the switch flipping. All stimuli that bring the membrane to threshold generate identical action potentials. In other words, the properties of the action potential are independent of the relative strength of the depolarizing stimulus, as long as that stimulus exceeds the threshold. This concept is called the **all-or-none principle** because a given stimulus triggers either a typical action potential or none. The all-or-none principle applies to all excitable membranes.

Generation of Action Potentials

Spotlight Figure 12–13 diagrams the steps involved in generating an action potential from the resting state. Recall that voltage-gated sodium ion channels are abundant on the axon,

Each neuron receives information in the form of graded potentials on its dendrites and cell body, and graded potentials at the synaptic terminals trigger the release of neurotransmitters. However, the two ends of the neuron may be a meter apart, and even the largest graded potentials affect only a tiny area. Such relatively long-range communication requires a different mechanism—the action potential. **Action potentials** are propagated changes in the membrane potential that, once initiated, affect an entire excitable membrane. Action potentials are dependent on the presence of both voltage-gated sodium and potassium ion channels.

Steps in the generation of an action potential at the initial segment of an axon.

The first step is a graded depolarization caused by the opening of chemically gated sodium ion channels, usually at the axon hillock. Note that when illustrating action potentials, we can ignore both the leak channels and the chemically gated channels, because their properties do not change. *The membrane colors in steps 1–4 match the colors of the line graph showing membrane potential changes.*

RESTING MEMBRANE POTENTIAL

The axolemma contains both voltage-gated sodium channels and voltage-gated potassium channels that are closed when the membrane is at the resting membrane potential.

KEY

- ⊕ = Sodium ion (Na^+)
- ⊕ = Potassium ion (K^+)

1 Depolarization to Threshold

The stimulus that initiates an action potential is a graded depolarization large enough to open voltage-gated sodium channels. The opening of the channels occurs at a membrane potential known as the threshold.

2 Activation of Sodium Ion Channels and Rapid Depolarization

When the sodium channel activation gates open, the plasma membrane becomes much more permeable to Na^+ . Driven by the large electrochemical gradient, sodium ions rush into the cytosol, and rapid depolarization occurs. The inner membrane surface now has more positive ions than negative ones, and the membrane potential has changed from -60 mV to a positive value.

Changes in the membrane potential at one location during the generation of an action potential.

The circled numbers in the graph correspond to the step art in this figure. It provides a timeline of the membrane potential changes.

3 Inactivation of Sodium Ion Channels and Activation of Potassium Ion Channels Starts Repolarization

As the membrane potential approaches +30 mV, the inactivation gates of the voltage-gated sodium channels close. This step is known as **sodium channel inactivation**, and it coincides with the opening of voltage-gated potassium channels. Positively charged potassium ions move out of the cytosol, shifting the membrane potential back toward the resting level. Repolarization now begins.

4 Time Lag in Closing All Potassium Ion Channels Leads to Temporary Hyperpolarization

The voltage-gated sodium channels remain inactivated until the membrane has repolarized to near threshold level. At this time, they regain their normal status: closed but capable of opening. The voltage-gated potassium channels begin closing as the membrane reaches the normal resting membrane potential (about -70 mV). Until all of these potassium channels have closed, potassium ions continue to leave the cell. This produces a brief hyperpolarization.

RESTING MEMBRANE POTENTIAL

After all the voltage-gated potassium channels close, the membrane potential returns to the normal resting level. The action potential is now over, and the membrane is once again at the resting membrane potential.

its branches, and its axon terminals. At the resting membrane potential, the activation gates of the voltage-gated sodium ion channels are closed. Once the membrane reaches threshold, the first step in generating an action potential is the opening of voltage-gated sodium ion channels at one site, usually the initial segment of the axon. The steps then proceed as follows: (1) depolarization to threshold; (2) activation of voltage-gated sodium ion channels and rapid depolarization; (3) inactivation of voltage-gated sodium ion channels and activation of voltage-gated potassium ion channels, beginning repolarization; and (4) closing of voltage-gated potassium ion channels, producing a brief hyperpolarization (due to a lag in total closing of channels), and then a return to the resting membrane potential. Spend some time with this figure before going on.

Table 12-3 reviews the key differences between graded potentials and action potentials.

The Refractory Period

The plasma membrane does not respond normally to additional depolarizing stimuli from the time an action potential begins until the resting membrane potential has been reestablished. This period is known as the **refractory period** of the membrane. From the moment the voltage-gated sodium ion channels open at threshold until sodium ion channel inactivation ends, the membrane cannot respond to further stimulation because all the voltage-gated sodium ion channels either are already open or are inactivated. This first part of the refractory period, called the **absolute refractory period**, lasts 0.4–1.0 msec.

The **relative refractory period** begins when the sodium ion channels regain their normal resting condition and continues until the membrane potential stabilizes at the resting

level. Another action potential can occur during this period if the membrane is sufficiently depolarized. That depolarization, however, requires a larger-than-normal stimulus, because (1) the local current must deliver enough Na^+ to counteract the exit of positively charged K^+ through open voltage-gated K^+ channels, and (2) the membrane is hyperpolarized to some degree through most of the relative refractory period.

Tips

Flushing a toilet provides a useful analogy for an action potential and its refractory period. Nothing happens while pressing the handle, until the water starts to flow (threshold is reached). After that, the amount of water that is released is independent of how hard or quickly the handle is pressed (all-or-none principle). Finally, the toilet cannot be flushed again until the tank refills (refractory period).

The Role of the Sodium–Potassium Exchange Pump

In an action potential, depolarization results from the influx of Na^+ , and repolarization involves the loss of K^+ . Over time, the sodium–potassium exchange pump returns the intracellular and extracellular concentrations of these ions to resting state levels. However, compared with the total number of ions inside and outside the cell, the number of ions involved in a single action potential is insignificant. Tens of thousands of action potentials can occur before intracellular ion concentrations change enough to disrupt the entire mechanism. For this reason, the exchange pump is not essential to any single action potential.

However, a maximally stimulated neuron can generate action potentials at a rate of 1000 per second. Under these circumstances, the exchange pump is needed to keep ion concentrations within acceptable limits over a prolonged period. The sodium–potassium exchange pump requires energy in the form of ATP. Each time the pump exchanges two extracellular potassium ions for three intracellular sodium ions, one molecule of ATP is broken down. Recall that the membrane protein of the exchange pump is $\text{Na}^+/\text{K}^+ \text{ATPase}$, which gets the energy to pump ions by splitting a phosphate group from a molecule of ATP, forming ADP. If the cell uses all its ATP, or if a metabolic poison inactivates $\text{Na}^+/\text{K}^+ \text{ATPase}$, the neuron will soon stop functioning.

Propagation of Action Potentials

The events that generate an action potential take place in a small portion of the total plasma membrane surface. But unlike graded potentials, action potentials spread along the entire excitable membrane. To understand how this happens, imagine someone is by the doors of a store at the start of a long line. Everyone is waiting for the doors to open.

Table 12-3 A Comparison of Graded Potentials and Action Potentials

Graded Potentials	Action Potentials
Depolarizing or hyperpolarizing	Always depolarizing
No threshold level	Depolarization to threshold level must occur before action potential begins
Amount of depolarization or hyperpolarization depends on intensity of stimulus; summation occurs	All-or-none event; all stimuli that exceed threshold produce identical action potentials; no summation occurs
Passive spread outward from site of stimulation	Action potential at one site depolarizes adjacent sites to threshold level
Effect on membrane potential decreases with distance from stimulation site	Propagated along entire membrane surface without decrease in strength
No refractory period	Refractory period occurs
Occur in most plasma membranes	Occur only in excitable membranes of specialized cells such as neurons and muscle cells

The manager steps outside and says to the crowd, “Let everyone know that we’re opening in 15 minutes.” How would the news spread?

If the line of people were treated as an unexcitable membrane, a person would shout, “The doors open in 15 minutes!” as loudly as they could. The closest people in the line would hear the news very clearly, but those farther away might not hear the entire message, and those at the end of the line might not hear the person at all.

If, however, the crowd were treated as an excitable membrane, the first person would tell the message to the next person in line, with instructions to pass it on. In that way, the message would travel along the line undiminished until everyone had heard the news. Such a message “moves” as each person repeats it to someone else. Distance is not a factor; the line can contain 50 people or 5000.

Having each person repeat the message is comparable to the way an action potential spreads along an excitable membrane. An action potential (message) is relayed from one location to another in a series of steps. At each step, the message is repeated. Because the same events take place over and over, the term **propagation** is preferable to the term *conduction*, which suggests a flow of charge similar to that in a conductor such as a copper wire. (In fact, compared to wires, axons are poor conductors of electricity.)

Types of Propagation

When sodium ions move into an axon and depolarize adjacent sites, this triggers the opening of additional voltage-gated sodium ion channels. The result is a chain reaction that spreads across the surface of the membrane like a line of falling dominoes. In this way, the action potential is propagated along the length of the axon, ultimately reaching the axon terminals.

Action potentials may travel along an axon in two ways: by *continuous propagation* (unmyelinated axons) or by *saltatory propagation* (myelinated axons). Let’s explore the similarities and differences between these two types of propagation.

Continuous Propagation. In an unmyelinated axon, an action potential moves along by **continuous propagation** (Spotlight Figure 12–14a). As you learn the steps of this process, for convenience, think of the axolemma (axon membrane) as a series of adjacent segments.

As mentioned earlier, the action potential begins at the axon’s initial segment. For a brief moment at the peak of the action potential, the membrane potential becomes positive rather than negative (1). A local current then develops as sodium ions begin moving from the extracellular fluid into the cytosol (2). The local current spreads in all directions, depolarizing adjacent portions of the membrane. (The axon hillock cannot respond with an action potential because, like the rest of the cell body, it lacks voltage-gated sodium ion channels.) The process then continues in a chain reaction (3 and 4).

Each time a local current develops, the action potential moves forward, but not backward, because the previous segment of the axon is still in the absolute refractory period. As a result, an action potential always proceeds away from the site of generation and cannot reverse direction. Eventually, the most distant portions of the plasma membrane are affected.

As in our “store line” model, the message is relayed from one location to another. At each step along the way, the message is retold, so distance has no effect on the process. The action potential reaching the axon terminal is identical to the one generated at the initial segment. The net effect is the same as if a single action potential had traveled across the surface of the membrane.

In continuous propagation, an action potential appears to move across the surface of the membrane in a series of tiny steps. Even though the events at any one location take only about a millisecond, they must be repeated at each step along the way. Continuous propagation along unmyelinated axons occurs at a speed of about 1 meter per second (approximately 2 mph). For a second action potential to occur at the same site, a second stimulus must be applied.

Tips

The “wave” performed by fans in a football stadium illustrates the continuous propagation of an action potential. The “wave” moves, but the people remain in place.

Saltatory Propagation. An action potential in a myelinated axon moves by **saltatory propagation** (*saltare*, leaping) (Spotlight Figure 12–14b). Saltatory propagation in the CNS and PNS carries action potentials along an axon much more rapidly than does continuous propagation. To get the general idea, let’s return to the line in front of the store, and assume that it takes 1 second to relay the message to another person. In a model of continuous propagation, the people are jammed together. In 4 seconds, four people would hear the news, and the message would move perhaps 2 meters along the line. In a model of saltatory propagation, in contrast, the people in the line are spaced 5 meters apart. In this case, after 4 seconds the same message would move 20 meters.

In a myelinated axon, the “people” are the nodes, and the spaces between them are the internodes wrapped in myelin (Figure 12–6a). Continuous propagation cannot occur along a myelinated axon, because myelin increases resistance to the flow of ions across the membrane. Ions can readily cross the axolemma only at the nodes. As a result, only the nodes with their voltage-gated ion channels can respond to a depolarizing stimulus.

When an action potential appears at the initial segment of a myelinated axon, the local current skips the internodes and depolarizes the closest node to threshold. Because the nodes may be 1–2 mm apart in a large, myelinated axon, the action potential “jumps” from node to node rather than moving

a Continuous Propagation along an Unmyelinated Axon

In an unmyelinated axon, an action potential moves along by continuous propagation. The action potential spreads by depolarizing the adjacent region of the axon membrane (axolemma). This process continues to spread as a chain reaction down the axon.

1

As an action potential develops at the initial segment ①, the membrane potential at this site depolarizes to +30 mV.

2

A local current then develops as the sodium ions entering at ① spread away from the open voltage-gated channels. A graded depolarization quickly brings the axon membrane (axolemma) in segment ② to threshold.

3

An action potential now occurs in segment ② while segment ① begins repolarization.

4

As the sodium ions entering at segment ② spread laterally, a graded depolarization quickly brings the membrane in segment ③ to threshold, and the cycle is repeated.

■ Saltatory Propagation along a Myelinated Axon

Because myelin limits the movement of ions across the axon membrane (axolemma), the action potential must “jump” from node to node during propagation. This results in much faster propagation along the axon.

1

An action potential has occurred at the initial segment ①.

2

A local current produces a graded depolarization that brings the axon membrane (axolemma) at the next node to threshold.

3

An action potential develops at node ②.

4

A local current produces a graded depolarization that brings the axolemma at node ③ to threshold.

along the axon in a series of tiny steps. In addition to being faster, saltatory propagation uses proportionately less energy, because less surface area is involved and fewer sodium ions must be pumped out of the cytoplasm.

Axon Diameter and Propagation Speed

As we have read, myelin greatly increases the propagation speed of action potentials. The diameter of the axon also affects the propagation speed, although less dramatically. Axon diameter is important because ions must move through the cytosol in order to depolarize adjacent portions of the plasma membrane. Cytosol offers much less resistance to ion movement than does the axolemma. In this instance, an axon behaves like an electrical cable: The larger the diameter, the lower the resistance. (This is why motors with large current demands, such as the starter on a car, an electric stove, or a big air conditioner, use such thick wires.)

We can classify axons into three groups according to the relationships among their diameter, myelination, and propagation speed:

1. **Type A fibers** are the largest myelinated axons, with diameters ranging from 4 to 20 μm . These fibers carry action potentials at speeds of up to 120 meters per second (m/sec), or 268 mph.
2. **Type B fibers** are smaller myelinated axons, with diameters of 2–4 μm . Their propagation speeds average around 18 m/sec (about 40 mph).
3. **Type C fibers** are unmyelinated and less than 2 μm in diameter. These axons propagate action potentials at the leisurely pace of 1 m/sec (only 2 mph).

The advantage of myelin becomes clear when you compare Type C to Type A fibers and note that the diameter increases 10-fold but the propagation speed increases 120 times.

The different structures and propagation speeds of each type of fiber lend themselves to different functions. Type A fibers carry sensory information about position and balance, as well as delicate touch and pressure sensations from the skin surface to the CNS. The motor neurons that control skeletal muscles also send their commands over large, myelinated Type A axons. Type B fibers and Type C fibers carry information to and from the CNS. They deliver temperature, pain, and general touch and pressure sensations. They also carry instructions to smooth muscle, cardiac muscle, glands, and other peripheral effectors.

Why isn't every axon in the nervous system large and myelinated? The most likely reason is that it would be physically impossible. If all sensory information were carried by large Type A fibers, the peripheral nerves would be the size of garden hoses, and the spinal cord would be the diameter of a garbage can. Instead, only about one-third of all axons carrying sensory information are myelinated, and most sensory information arrives over slender Type C fibers.

In essence, information transfer in the nervous system represents a compromise between propagation time and available space. Messages are routed according to priority: Urgent news—sensory information about things that threaten survival and motor commands that prevent injury—travels over Type A fibers (the equivalent of instant messaging or texting). Less urgent sensory information and motor commands are relayed by Type B fibers (e-mail) or Type C fibers (regular “snail mail”).

Checkpoint

15. Define action potential.
16. Identify the steps involved in the generation and propagation of an action potential.
17. What is the relationship between myelin and the propagation speed of action potentials?
18. Which of the following axons is myelinated: one that propagates action potentials at 50 meters per second or one that carries them at 1 meter per second?

See the blue Answers tab at the back of the book.

12-6 Synapses transmit signals among neurons or between neurons and other cells

Learning Outcome Describe the structure of a synapse, and explain the mechanism involved in synaptic activity.

In the nervous system, messages move from one location to another in the form of action potentials along axons. To be effective, a message must be not only propagated along an axon but also transferred in some way to another cell. This transfer takes place at a **synapse**, a specialized site where the neuron communicates with another cell.

At a synapse between two neurons, information passes from the *presynaptic neuron* to the *postsynaptic neuron*. Synapses may also involve other types of postsynaptic cells. For example, the neuromuscular junction is a synapse in which the postsynaptic cell is a skeletal muscle fiber.

Now let's take a closer look at the ways that synapses work. In this section, we first explore types of synapses, and then examine the function of chemical synapses with an example of the most common type in the body.

Types of Synapses

There are two types of synapses, *electrical* and *chemical*. Let's consider their similarities and differences.

Electrical Synapses

At **electrical synapses**, there is direct physical contact between the cells. The presynaptic and postsynaptic membranes of the two communicating cells are locked together at gap junctions. The lipid portions of adjacent membranes, separated by only

2 nm (0.002 μm), are held in position by binding between integral membrane proteins in these junctions called *connexons*. These proteins form pores that permit ions to pass between the cells. Because the two cells are linked in this way, changes in the membrane potential of one cell produce local currents that affect the other cell as if the two shared a common membrane. As a result, an electrical synapse propagates action potentials quickly and efficiently from one cell to the next.

Electrical synapses are extremely rare in both the adult CNS and PNS. They occur in some areas of the brain, including the vestibular nuclei (involved in balance), the eye, and in at least one pair of PNS ganglia (the ciliary ganglia, which control pupil constriction in the eyes). They do occur in some embryonic structures as well.

Chemical Synapses

A **chemical synapse** is where one neuron sends chemical signals to another cell, often a second neuron. Every chemical synapse involves two cells: (1) the axon terminal of the **pre-synaptic cell**, which sends a message, and (2) the **postsynaptic cell**, which receives the message. A narrow space called the **synaptic cleft** separates the two cells (**Figure 12-15**).

The presynaptic cell is usually a neuron. (Specialized receptor cells may form synaptic connections with the dendrites of neurons, a topic described in Chapter 15.) The postsynaptic cell can be either a neuron or another type of cell. One neuron may communicate with another at a synapse on a dendrite, on the cell body, or along the length of the axon of the receiving cell. At an *axoaxonic synapse*, a synapse occurs between the axons of two neurons. At an *axosomatic synapse*, the junction occurs at the axon terminal of one neuron with the cell body of another; at an *axodendritic synapse*, the synaptic

contact is between the axon terminal of one neuron and the dendrite of another neuron. A synapse between a neuron and a skeletal muscle cell is called a **neuromuscular junction**. At a **neuroglandular junction**, a neuron controls or regulates the activity of a secretory (gland) cell. Neurons also *innervate* (are distributed to) a variety of other cell types, such as adipocytes (fat cells). We consider the nature of that innervation in later chapters.

The axon terminal of the presynaptic cell releases chemicals called **neurotransmitters** into the synaptic cleft. Inside the axon terminal, neurotransmitters are contained in *synaptic vesicles*.

The structure of the axon terminal varies with the type of postsynaptic cell. A relatively simple, round axon terminal occurs where the postsynaptic cell is another neuron. At a synapse, the narrow synaptic cleft separates the presynaptic membrane, where neurotransmitters are released, from the postsynaptic membrane, which bears receptors for neurotransmitters (**Figure 12-15**). The axon terminal at a neuromuscular junction is much more structurally complex.

Each axon terminal contains mitochondria and thousands of vesicles filled with neurotransmitter molecules. The axon terminal reabsorbs breakdown products of neurotransmitters formed at the synapse and reassembles them. It also receives a continuous supply of neurotransmitters synthesized in the cell body, along with enzymes and lysosomes, by anterograde flow.

Chemical synapses are by far the most abundant type of synapse. Most synapses among neurons, and all communications between neurons and other types of cells, involve chemical synapses. Normally, communication across a chemical synapse takes place in only one direction: from the presynaptic membrane to the postsynaptic membrane.

12

Figure 12-15 The Structure of a Typical Chemical Synapse.

Function of Chemical Synapses

Neurotransmitter release is triggered by electrical events, such as the arrival of an action potential. The presynaptic cell typically releases neurotransmitters. The neurotransmitters then flood the synaptic cleft and bind to receptors on the postsynaptic plasma membrane, changing its permeability and producing graded potentials. The mechanism is comparable to that of the neuromuscular junction, described in Chapter 10.

The situation at a chemical synapse is far more variable than that at an electrical synapse because the cells are not directly coupled. For example, an action potential that reaches an electrical synapse is *always* propagated to the next cell. But at a chemical synapse, an arriving action potential *may or may not* release enough neurotransmitter to bring the postsynaptic neuron to threshold. In addition, other factors may intervene and make the postsynaptic cell more sensitive or less sensitive to arriving stimuli. In essence, the postsynaptic cell at a chemical synapse is not dependent on the presynaptic neuron, and its activity can be adjusted, or “tuned,” by a variety of factors.

Here, we continue our discussion of chemical synapses with a look at a synapse that releases the neurotransmitter **acetylcholine (ACh)**. The next section (Section 12-7) introduces additional neurotransmitters that you will read about in later chapters.

Example of Chemical Synaptic Function: Cholinergic Synapses

Synapses that release ACh are known as **cholinergic** (kol-in-ER-jik) **synapses**. ACh is the most widespread (and best-studied) neurotransmitter. It is released at (1) all neuromuscular junctions involving skeletal muscle fibers, (2) many synapses in the CNS, (3) all neuron-to-neuron synapses in the PNS, and (4) all neuromuscular and neuroglandular junctions in the parasympathetic division of the ANS.

Tips

Cholinergic synapses are so named because the neurotransmitter involved is **acetylcholine**.

12

At a cholinergic synapse between two neurons, the presynaptic and postsynaptic membranes are separated by a synaptic cleft that averages 20 nm (0.02 μm) in width. Most of the ACh in the axon terminal is packaged in synaptic vesicles, each containing several thousand molecules of the neurotransmitter. A single axon terminal may contain a million such vesicles. Let's look at events at the cholinergic synapse, including how the neurotransmitter is released, its diffusion across the synapse, and its binding to receptors in a process known as *synaptic delay*. We conclude with *synaptic fatigue*, the short-term inability of a neuron to generate an action potential.

Figure 12-16 diagrams the events that take place at a cholinergic synapse between neurons after an action potential arrives at an axon terminal. For simplicity, we will assume that this synapse is adjacent to the initial segment of the axon.

- 1 **An Action Potential Arrives at the Presynaptic Axon Terminal and Depolarizes the Membrane.**
- 2 **Extracellular Calcium Ions Enter the Axon Terminal, Triggering the Exocytosis of ACh within Synaptic Vesicles.** The depolarization of the axon terminal briefly opens its voltage-gated calcium ion channels, allowing calcium ions to rush in. Their arrival triggers exocytosis of synaptic vesicles containing ACh into the synaptic cleft.

The ACh is released in packets of about 3000 molecules, the average number of ACh molecules in a single vesicle. ACh release stops very soon, because active transport mechanisms rapidly remove the calcium ions from the cytosol in the axon terminal. The calcium ions are either pumped out of the cell or absorbed by mitochondria.

- 3 **ACh Binds to Receptors on the Postsynaptic Membrane and Depolarizes the Membrane.** ACh diffuses across the synaptic cleft

toward receptors on the postsynaptic membrane. These ACh receptors are chemically gated cation (Na^+ , K^+) channels. The primary response is an increased permeability to Na^+ , producing a depolarization in the postsynaptic membrane that lasts about 20 msec. (These cation channels also let potassium ions out of the cell, but because sodium ions are driven by a much stronger electrochemical gradient, the net effect is a slight depolarization of the postsynaptic membrane.)

This depolarization is a graded potential. The greater the amount of ACh released at the presynaptic membrane, the greater the number of open cation channels in the postsynaptic membrane, and so the larger the depolarization. If the depolarization brings an adjacent area of excitable membrane (such as the initial segment of an axon) to threshold, an action potential occurs in the postsynaptic neuron.

- 4 **ACh Is Removed from the Synaptic Cleft by AChE.** The neurotransmitter's effects on the postsynaptic membrane are temporary because the synaptic cleft and the postsynaptic membrane contain the enzyme *acetylcholinesterase* (AChE, or *cholinesterase*). Approximately half of the ACh released at the presynaptic membrane is broken down before it reaches receptors on the postsynaptic membrane. ACh molecules that bind to receptor sites are generally broken down within 20 msec of their arrival.

AChE breaks down molecules of ACh (by hydrolysis) into **acetate** and **choline**. The choline is actively absorbed by the axon terminal and is used to synthesize more ACh, using acetate provided by *coenzyme A* (CoA). (Recall from Chapter 2 that coenzymes [derived from vitamins] are required in many enzymatic reactions.) Acetate diffusing away from the synapse can be absorbed and metabolized by the postsynaptic cell or by other cells and tissues.

Synaptic Delay

A **synaptic delay** of 0.2–0.5 msec occurs between the arrival of the action potential at the axon terminal and the effect on the postsynaptic membrane. Most of that delay reflects the time involved in calcium ion influx and neurotransmitter release, not in the neurotransmitter's diffusion—the synaptic cleft is narrow, and neurotransmitters can quickly diffuse across it.

Although a delay of 0.5 msec is not very long, in that time an action potential may travel more than 7 cm (about 3 in.) along a myelinated axon. When information is being passed along a chain of interneurons in the CNS, the cumulative synaptic delay may exceed the propagation time along the axons.

This is why reflexes are important for survival—they involve only a few synapses and thus provide rapid and automatic responses to stimuli. The fewer synapses involved, the shorter the total synaptic delay and the faster the response. The fastest reflexes have just one synapse, with a sensory neuron directly controlling a motor neuron (Chapter 13 has examples).

Figure 12–16 Events in the Functioning of a Cholinergic Synapse.

Which part of an acetylcholine (ACh) molecule undergoes reuptake by the axon terminal for use in another acetylcholine molecule?

Synaptic Fatigue

Because ACh molecules are recycled, the axon terminal is not totally dependent on the ACh synthesized in the cell body and delivered by axonal transport. But under intensive stimulation, resynthesis and transport mechanisms may not keep up with the demand for neurotransmitter. **Synaptic fatigue** then occurs, and the response of the synapse weakens until ACh has been replenished.

12-7 The effects of neurotransmitters and neuromodulators depend on their receptors

Learning Outcome Describe the major types of neurotransmitters and neuromodulators and discuss their effects on postsynaptic membranes.

Now that we have examined the actions of acetylcholine at cholinergic synapses, let's consider the actions of other neurotransmitters and of *neuromodulators*, which change the cell's response to neurotransmitters.

The nervous system relies on a complex form of chemical communication. Each neuron is continuously exposed to a variety of neurotransmitters. Acetylcholine (ACh) is the neurotransmitter that has received most of our attention so far, but there are other important chemical transmitters. Based on their effects on postsynaptic membranes, neurotransmitters are often classified as excitatory or inhibitory. **Excitatory neurotransmitters** cause depolarization and promote the generation of action potentials. **Inhibitory neurotransmitters** cause hyperpolarization and suppress the generation of action potentials.

This classification is useful, but not always precise. For example, acetylcholine typically produces a depolarization in the postsynaptic membrane, but acetylcholine released at neuromuscular junctions in the heart has an inhibitory effect, producing a transient hyperpolarization of the postsynaptic membrane. This situation highlights an important aspect of neurotransmitter function: *The effect of a neurotransmitter on the*

postsynaptic membrane depends on the properties of the receptor, not on the nature of the neurotransmitter.

Let's first explore how neurotransmitters and neuromodulators are categorized and then discuss their receptor-dependent functions.

Classes of Neurotransmitters and Neuromodulators

Major classes of neurotransmitters include *biogenic amines*, *amino acids*, *neuropeptides*, *dissolved gases*, and a variety of other compounds. Here we introduce only a few of the most important neurotransmitters. Additional examples are given in later chapters.

Biogenic Amines

- **Norepinephrine** (nor-ep-i-NEF-rin), or **NE**, is a neurotransmitter that is widely distributed in the brain and in portions of the ANS. Norepinephrine is also called *noradrenaline*, and synapses that release NE are known as **adrenergic synapses**. Norepinephrine typically has an excitatory, depolarizing effect on the postsynaptic membrane, but the mechanism is quite distinct from that of ACh, as we find in Chapter 16.
- **Dopamine** (DŌ-puh-mēn) is a CNS neurotransmitter released in many areas of the brain. It may have either inhibitory or excitatory effects. Inhibitory effects play an important role in our precise control of movements. For example, dopamine release in one portion of the brain prevents the overstimulation of neurons that control skeletal muscle tone. If the neurons that produce dopamine are damaged or destroyed, the result can be the characteristic rigidity and stiffness of *Parkinson's disease*, a condition described in Chapter 14. At other sites, dopamine release has excitatory effects. For example, the stimulant drug cocaine inhibits the removal of dopamine from synapses in specific areas of the brain. The resulting rise in dopamine concentration at these synapses is responsible for the "high" experienced by users. (Please note that cocaine is a highly addictive drug that can have serious health effects.)
- **Serotonin** (ser-ō-TŌ-nin) is another important CNS neurotransmitter. Inadequate serotonin production can have widespread effects on a person's attention and emotional states and may be responsible for many cases of severe chronic depression. *Fluoxetine* (Prozac), *paroxetine* (Paxil), *sertraline* (Zoloft), and related antidepressant drugs inhibit the reabsorption of serotonin by axon terminals (hence their classification as selective serotonin reuptake inhibitors, or SSRIs). This inhibition leads to increased serotonin concentration at synapses, and over time, the increase may relieve the symptoms of depression. Interactions among serotonin, norepinephrine, and other neurotransmitters are thought to be involved in the regulation of sleep and wake cycles.

Amino Acids

- **Gamma aminobutyric** (a-MĒ-nō-bū-TĒR-ik) **acid**, or **GABA**, generally has an inhibitory effect. About 20% of the synapses in the brain release GABA, but its functions remain incompletely understood. In the CNS, GABA release appears to reduce anxiety, and some antianxiety drugs work by enhancing this effect.

Neuropeptides

It is convenient to discuss each synapse as if it were releasing only one neurotransmitter. However, axon terminals may release a mixture of active compounds, either through diffusion across the membrane or by exocytosis, along with neurotransmitter molecules. These compounds may have a variety of functions. Those that alter the rate of neurotransmitter release by the presynaptic neuron or change the postsynaptic cell's response to neurotransmitters are called **neuromodulators** (nū-rō-MOD-ū-lā-torz). These substances are typically **neuropeptides**, small peptide chains synthesized and released by the axon terminal. Most neuromodulators act by binding to receptors in the presynaptic or postsynaptic membranes and activating cytoplasmic enzymes. In general, neuromodulators (1) have long-term effects that are relatively slow to appear; (2) trigger responses that involve several steps and intermediary compounds; (3) may affect the presynaptic membrane, the postsynaptic membrane, or both; and (4) can be released alone or along with a neurotransmitter.

Neuromodulators called **opioids** (Ō-pē-oydz) have effects similar to those of the drugs *opium* and *morphine*, because they bind to the same group of postsynaptic receptors. Three main classes of opioids in the CNS are (1) **enkephalins** (en-KEF-a-linz), (2) **endorphins** (en-DOR-finz), and (3) **dynorphins** (DĪ-nor-finz). The primary function of opioids is probably to relieve pain. They inhibit the release of the neurotransmitter *substance P* at synapses that relay pain sensations. Dynorphins have far more powerful pain-relieving effects than morphine or the other opioids.

Tips

Endorphins are so named because they act like **endogenous** (coming from within the body) **morphine**.

Dissolved Gases

- In addition, two lipid-soluble gases, nitric oxide and carbon monoxide, are known to be important neurotransmitters. **Nitric oxide (NO)** is generated by axon terminals that innervate smooth muscle in the walls of blood vessels in the PNS, and at synapses in several regions of the brain. **Carbon monoxide (CO)**, best known as a component of automobile exhaust, is also generated by specialized axon terminals in the brain, where it functions as a neurotransmitter.

The functions of many neurotransmitters are not well understood. In a clear demonstration of the principle “the more you look, the more you see,” over 100 neurotransmitters have been identified, including certain amino acids, peptides, polypeptides, prostaglandins, and ATP.

Table 12–4 lists major neurotransmitters and neuromodulators of the brain and spinal cord and their primary effects (if known). In practice, it can be very difficult to distinguish neurotransmitters from neuromodulators on either biochemical or functional grounds: A neuropeptide may function in one site as a neuromodulator and in another as a neurotransmitter. For this reason, **Table 12–4** does not distinguish between neurotransmitters and neuromodulators.

The Functions of Neurotransmitters and Neuromodulators and Their Receptors

Functionally, neurotransmitters and neuromodulators fall into one of three groups: (1) compounds that have a *direct effect* on membrane potential, (2) compounds that have an *indirect effect* on membrane potential through G proteins, or (3) lipid-soluble gases that have an *indirect effect on membrane potential through intracellular enzymes*.

Direct Effects

Compounds that have direct effects on membrane potential open or close chemically gated ion channels (**Figure 12–17a**). Examples include ACh and the amino acids *glutamate* and *aspartate*. Because these neurotransmitters alter ion movement across the membrane, they are said to have *ionotropic* (ī-ō-nō-TRŌ-pik) *effects*.

A few neurotransmitters, notably glutamate, GABA, norepinephrine, and serotonin, have both direct and indirect effects, because these compounds target two different classes of receptors. The direct effects are ionotropic. The indirect effects, which involve changes in the metabolic activity of the postsynaptic cell, are called *metabotropic*.

Indirect Effects by Second Messengers

Compounds that have an indirect effect on membrane potential work through intermediaries known as *second messengers*. The neurotransmitter represents a *first messenger*, because it delivers the message to receptors on the plasma membrane or within the cell. Second messengers are ions or molecules that are produced or released inside the cell when a first messenger binds to one of these receptors.

Many neurotransmitters—epinephrine, norepinephrine, dopamine, serotonin, histamine, and GABA—and many neuromodulators bind to receptors in the plasma membrane called *G protein-coupled receptors* (GPCRs). The link between the first messenger and the second messenger is a **G protein**, an enzyme complex coupled to a membrane receptor.

Table 12–4 Representative Neurotransmitters and Neuromodulators

Class and Neurotransmitter	Chemical Structure	Mechanism of Action	Location(s)	Comments
Acetylcholine		Primarily direct, through binding to chemically gated ion channels	CNS: synapses throughout brain and spinal cord PNS: neuromuscular junctions; preganglionic synapses of ANS; neuroglandular junctions of parasympathetic division and (rarely) sympathetic division of ANS; amacrine cells of retina	Widespread in CNS and PNS; best known and most studied of the neurotransmitters
BIOGENIC AMINES				
Norepinephrine		Indirect: G proteins and second messengers	CNS: cerebral cortex, hypothalamus, brainstem, cerebellum, spinal cord PNS: most neuromuscular and neuroglandular junctions of sympathetic division of ANS	Involved in attention and consciousness, control of body temperature, and regulation of pituitary gland secretion
Epinephrine		Indirect: G proteins and second messengers	CNS: thalamus, hypothalamus, midbrain, spinal cord	Uncertain functions
Dopamine		Indirect: G proteins and second messengers	CNS: hypothalamus, midbrain, limbic system, cerebral cortex, retina	Regulation of subconscious motor function; receptor abnormalities have been linked to development of schizophrenia
Serotonin		Primarily indirect: G proteins and second messengers	CNS: hypothalamus, limbic system, cerebellum, spinal cord, retina	Important in emotional states, moods, and body temperature; several illegal hallucinogenic drugs, such as ecstasy, target serotonin receptors
Histamine		Indirect: G proteins and second messengers	CNS: neurons in hypothalamus, with axons projecting throughout the brain	Receptors are primarily on presynaptic membranes; functions in sexual arousal, pain threshold, pituitary hormone secretion, thirst, and blood pressure control
AMINO ACIDS				
Excitatory: Glutamate		Indirect: G proteins and second messengers Direct: opens calcium/sodium ion channels on pre- and postsynaptic membranes	CNS: cerebral cortex and brainstem	Important in memory and learning; most important excitatory neurotransmitter in the brain
Aspartate		Direct or indirect (G proteins), depending on type of receptor	CNS: cerebral cortex, retina, and spinal cord	Used by pyramidal cells in the brain that provide voluntary motor control over skeletal muscles
Inhibitory: Gamma aminobutyric acid (GABA)		Direct or indirect (G proteins), depending on type of receptor	CNS: cerebral cortex, cerebellum, interneurons throughout brain and spinal cord	Direct effects: open Cl ⁻ channels; indirect effects: open K ⁺ channels and block entry of Ca ²⁺
Glycine		Direct: opens Cl ⁻ channels	CNS: interneurons in brainstem, spinal cord, and retina	Produces postsynaptic inhibition; the poison <i>strychnine</i> produces fatal convulsions by blocking glycine receptors

(Continued)

Table 12–4 (continued)

Class and Neurotransmitter	Chemical Structure	Mechanism of Action	Location(s)	Comments
NEUROPEPTIDES				
Substance P		Indirect: G proteins and second messengers	CNS: synapses of pain receptors within spinal cord, hypothalamus, and other areas of the brain PNS: enteric nervous system (network of neurons along the digestive tract)	Important in pain pathway, regulation of pituitary gland function, control of digestive tract reflexes
Neuropeptide Y	36-amino-acid peptide	Indirect: G proteins and second messengers	CNS: hypothalamus PNS: sympathetic neurons	Stimulates appetite and food intake
Opioids	31-amino-acid peptide	Indirect: G proteins and second messengers	CNS: thalamus, hypothalamus, brainstem, retina	Pain control; emotional and behavioral effects poorly understood
Enkephalins		Indirect: G proteins and second messengers	CNS: basal nuclei, hypothalamus, midbrain, pons, medulla oblongata, spinal cord	Pain control; emotional and behavioral effects poorly understood
Endorphin	9- or 10-amino-acid peptide	Indirect: G proteins and second messengers	CNS: thalamus, hypothalamus, basal nuclei	Pain control; emotional and behavioral effects poorly understood
Dynorphin		Indirect: G proteins and second messengers	CNS: hypothalamus, midbrain, medulla oblongata	Pain control; emotional and behavioral effects poorly understood
PURINES				
ATP, GTP	(Figure 2–26)	Direct or indirect (G proteins), depending on type of receptor	CNS: spinal cord PNS: autonomic ganglia	
Adenosine	(Figure 2–26)	Indirect: G proteins and second messengers	CNS: cerebral cortex, hippocampus, cerebellum	Produces drowsiness; stimulatory effect of caffeine is due to inhibition of adenosine activity
HORMONES				
ADH, oxytocin, insulin, glucagon, secretin, CCK, GIP, VIP, inhibins, ANP, BNP, and many others	Peptide containing fewer than 200 amino acids	Typically indirect: G proteins and second messengers	CNS: brain (widespread)	Numerous, complex, and incompletely understood
GASES				
Carbon monoxide (CO)		Indirect: by diffusion to enzymes activating second messengers	CNS: brain PNS: some neuromuscular and neuroglandular junctions	Localization and function poorly understood
Nitric oxide (NO)		Indirect: by diffusion to enzymes activating second messengers	CNS: brain, especially at blood vessels PNS: some sympathetic neuromuscular and neuroglandular junctions	
LIPIDS				
Anandamide		Indirect: G proteins and second messengers	CNS: cerebral cortex, hippocampus, cerebellum	Euphoria, drowsiness, appetite; receptors are targeted by the active compound in marijuana

Figure 12–17 Mechanisms of Neurotransmitter and Receptor Function.

The name *G protein* refers to the fact that these proteins bind GTP, a high-energy compound introduced in Chapter 2. Several types of G protein exist, but each type includes an enzyme that is “turned on” when an extracellular compound binds to its associated receptor at the cell surface.

Figure 12–17b shows one possible result of this binding: the activation of the enzyme **adenylyl cyclase**. This enzyme converts ATP, the energy currency of the cell, to *cyclic-AMP* (cAMP), a ring-shaped form of the compound AMP that was introduced in Chapter 2. The conversion takes place at the inner, cytosolic surface of the plasma membrane. Cyclic-AMP is a second messenger that may open membrane ion channels, activate intracellular enzymes, or both, depending on the nature of the postsynaptic cell. This is only an overview of the function of one type of G protein. We examine several types of G proteins more closely in later chapters.

Indirect Effects by Intracellular Enzymes

The two lipid-soluble gases nitric oxide (NO) and carbon monoxide (CO) function as neurotransmitters in specific regions of the brain. Because they can diffuse through lipid membranes, these gases can enter the cell and bind to enzymes on the inner surface of the plasma membrane or elsewhere in the cytoplasm (**Figure 12–17c**). These enzymes then promote the appearance of second messengers that can affect cellular activity.

12-8 Individual neurons process information by integrating excitatory and inhibitory stimuli

Learning Outcome Discuss the interactions that enable information processing to occur in nervous tissue.

A single neuron may receive information across thousands of synapses. Some of the neurotransmitters arriving at the postsynaptic cell at any moment may be excitatory, and others may be inhibitory. So how does the neuron respond? The net effect on the membrane potential of the cell body—specifically, in the area of the axon hillock—determines how the neuron responds from moment to moment. If the net effect is a depolarization at the axon hillock, that depolarization affects the membrane potential at the initial segment. If threshold is reached at the initial segment, an action potential is generated and propagated along the axon. Therefore, at any given moment it is really the axon hillock that is integrating the excitatory and inhibitory stimuli affecting the cell body and dendrites. This integration process, which determines the rate of action potential generation at the initial segment, is the simplest level of **information processing** in the nervous system.

Once the signal gets to the postsynaptic cell, its response ultimately depends on what the stimulated receptors do and

what other stimuli are influencing the cell at the same time. The excitatory and inhibitory stimuli are integrated through interactions between *postsynaptic potentials*, which we discuss in this section. Presynaptic inhibition, presynaptic facilitation, and the rate of action potential generation are also discussed. Higher levels of information processing involve interactions among neurons and among groups of neurons. These topics are addressed in later chapters.

Postsynaptic Potentials

Postsynaptic potentials are graded potentials that develop in the postsynaptic membrane in response to a neurotransmitter. (Figure 12-12 contrasted graded depolarization with hyperpolarization.) Two major types of postsynaptic potentials develop at neuron-to-neuron synapses: excitatory postsynaptic potentials and inhibitory postsynaptic potentials.

An **excitatory postsynaptic potential**, or **EPSP**, is a graded depolarization caused by the arrival of a neurotransmitter at the postsynaptic membrane. An EPSP results from the opening of chemically gated ion channels in the plasma membrane that lead to membrane depolarization. For example, the graded depolarization produced by the binding of ACh is an EPSP. Because it is a graded potential, an EPSP affects only the area immediately surrounding the synapse.

We have already noted that not all neurotransmitters have an excitatory (depolarizing) effect. An **inhibitory postsynaptic potential**, or **IPSP**, is a graded hyperpolarization of the postsynaptic membrane. For example, an IPSP may result from the opening of chemically gated potassium ion channels. While the hyperpolarization continues, the neuron is said to be **inhibited**, because a larger-than-usual depolarizing stimulus is needed to bring the membrane potential to threshold. A stimulus that shifts the membrane potential by 10 mV (from -70 mV to -60 mV) would normally produce an action potential, but if the membrane potential were reset at -85 mV by an IPSP, the same stimulus would depolarize it to only -75 mV, which is below threshold.

Integrating Postsynaptic Potentials: Summation

An individual EPSP has a small effect on the membrane potential, typically producing a depolarization of about 0.5 mV at the postsynaptic membrane. Before an action potential will arise in the initial segment, local currents must depolarize that region by at least 10 mV. Therefore, a single EPSP will not result in an action potential, even if the synapse is on the axon hillock. But individual EPSPs combine through the process of **summation**, which integrates the effects of all the graded potentials that affect one portion of the plasma membrane. The graded potentials may be EPSPs, IPSPs, or both. We focus on EPSPs in our present discussion. Two forms of summation exist: temporal summation and spatial summation (Figure 12-18).

Temporal Summation. **Temporal summation** (*tempus*, time) is the addition of stimuli occurring in rapid succession at a

single synapse that is active *repeatedly*. This form of summation can be likened to using a bucket to fill up a bathtub: While one can't fill the tub with a single bucket of water, it will fill eventually if one keeps repeating the process. In the case of temporal summation, the water in a bucket corresponds to the sodium ions that enter the cytosol during an EPSP. A typical EPSP lasts about 20 msec, but under maximum stimulation an action potential can reach the axon terminal each millisecond.

Figure 12-18a shows what happens when a second EPSP arrives before the effects of the first EPSP have disappeared: The effects of the two are combined. Every time an action potential arrives, a group of vesicles discharges ACh into the synaptic cleft, and every time more ACh molecules arrive at the postsynaptic membrane, more chemically gated ion channels open, and the degree of depolarization increases. In this way, a series of small steps can eventually bring the initial segment to threshold.

Spatial Summation. **Spatial summation** occurs when simultaneous stimuli applied at different locations have a cumulative effect on the membrane potential. In other words, spatial summation involves *multiple synapses* that are active *simultaneously*. In terms of our bucket analogy, one could fill the bathtub immediately if 10 others all emptied their buckets into it at the same time.

In spatial summation, more than one synapse is active at the same time (Figure 12-18b), and each "pours" sodium ions across the postsynaptic membrane, producing a graded potential with localized effects. At each active synapse, the sodium ions that produce the EPSP spread out along the inner surface of the membrane and mingle with those entering at other synapses. As a result, the effects on the initial segment are cumulative. The degree of depolarization depends on how many synapses are active at any moment and on their distance from the initial segment. As in temporal summation, an action potential results when the membrane potential at the initial segment reaches threshold.

Facilitation of Neurons

Now consider a situation in which summation of EPSPs is under way, but the initial segment has not been depolarized to threshold. The closer the initial segment gets to threshold, the easier it will be for the *next* depolarizing stimulus to trigger an action potential. A neuron whose membrane potential shifts closer to threshold is said to be **facilitated**. The larger the degree of facilitation, the smaller the additional stimulus needed to trigger an action potential. In a highly facilitated neuron, even a small depolarizing stimulus produces an action potential.

Facilitation can result from the summation of EPSPs or from the exposure of a neuron to certain drugs in the extracellular fluid. For example, the nicotine in cigarettes stimulates postsynaptic ACh receptors, producing prolonged EPSPs that facilitate CNS neurons. Nicotine also increases the release of another neurotransmitter, dopamine, producing feelings of pleasure and reward, thereby leading to addiction.

Figure 12–18 Temporal and Spatial Summation.

Figure 12–19 Interactions between EPSPs and IPSPs. At time 1, a small depolarizing stimulus produces an EPSP. At time 2, a small hyperpolarizing stimulus produces an IPSP of comparable magnitude. If the two stimuli are applied simultaneously, as they are at time 3, summation occurs. Because the two are equal in size but have opposite effects, the membrane potential remains at the resting level. If the EPSP were larger, a net depolarization would result; if the IPSP were larger, a net hyperpolarization would result instead.

Summation of EPSPs and IPSPs

Like EPSPs, IPSPs combine spatially and temporally. EPSPs and IPSPs reflect the activation of different types of chemically gated ion channels, producing opposing effects on the membrane potential. The antagonism between IPSPs and EPSPs is important in cellular information processing. Using our bucket analogy, EPSPs put water into the bathtub, and IPSPs take water out. If more buckets add water than remove water, the water level in the tub rises. If more buckets remove water, the level falls. If a bucket of water is removed every time another bucket is dumped in, the level remains stable. Comparable interactions between EPSPs and IPSPs determine the membrane potential at the boundary between the axon hillock and the initial segment (Figure 12-19).

Neuromodulators, hormones, or both can change the postsynaptic membrane's sensitivity to excitatory or inhibitory neurotransmitters. By shifting the balance between EPSPs and IPSPs, these compounds promote facilitation or inhibition of CNS and PNS neurons.

Presynaptic Regulation: Inhibition and Facilitation

Inhibitory or excitatory responses may occur not only at postsynaptic neurons but also at presynaptic neurons. An axoaxonic (axon to axon) synapse at the axon terminal can either decrease (inhibit) or increase (facilitate) the rate of neurotransmitter release at the presynaptic membrane. In one form of **presynaptic inhibition**, the release of GABA inhibits the opening of voltage-gated calcium ion channels in the axon terminal (Figure 12-20a). This inhibition reduces the amount of neurotransmitter released when an action potential arrives there, and thus reduces the effects of synaptic activity on the postsynaptic membrane.

In **presynaptic facilitation**, activity at an axoaxonic synapse increases the amount of neurotransmitter released when an action potential arrives at the axon terminal (Figure 12-20b). This increase enhances and prolongs the neurotransmitter's effects on the postsynaptic membrane. The neurotransmitter *serotonin* is involved in presynaptic facilitation. In the presence of serotonin released at an axoaxonic synapse, voltage-gated calcium ion channels remain open longer.

Figure 12-20 Presynaptic Inhibition and Presynaptic Facilitation at an Axoaxonic Synapse.

The Rate of Action Potential Generation

In the nervous system, complex information is translated into action potentials that are propagated along axons. On arrival, the message is often interpreted solely based on the frequency of action potentials. For example, action potentials arriving at a neuromuscular junction at the rate of 1 per second may produce a series of isolated twitches in the associated skeletal muscle fiber, but at the rate of 100 per second they cause a sustained tetanic contraction. Similarly, a person may perceive a few action potentials per second along a sensory fiber as a feather-light touch, but they would perceive hundreds of action potentials per second along that same axon as unbearable pressure. In general, the degree of sensory stimulation or the strength of the motor response is proportional to the frequency of action potentials. In this section, we examine factors that vary the rate of generation of action potentials.

If a graded potential briefly depolarizes the axon hillock such that the initial segment reaches its threshold, an action potential is generated. But what happens when the axon hillock *remains* depolarized past threshold for an extended period? The longer the initial segment remains above threshold, the more action potentials it produces. The *frequency* of action potentials depends on the degree of depolarization above threshold: The greater the degree of depolarization, the higher the frequency of action potentials. The membrane can respond to a second stimulus as soon as the absolute refractory period ends. Holding the membrane potential above threshold has the same effect as applying a second, larger-than-normal stimulus.

Action potentials can be generated at a maximum rate when the relative refractory period has been completely eliminated. For this reason, the maximum theoretical frequency of action potentials is established by the duration of the absolute refractory period. The absolute refractory period is shortest in large-diameter axons, in which the *theoretical* maximum frequency of action potentials is 2500 per second. However, the highest frequencies recorded from axons in the body range between 500 and 1000 per second.

Table 12-5 Information Processing

- Information is relayed in the form of action potentials. In general, the degree of sensory stimulation or the strength of the motor response is proportional to the frequency of action potentials.
- The neurotransmitters released at a synapse may have either excitatory or inhibitory effects. The effect on the axon's initial segment reflects a summation of the stimuli that arrive at any moment. The frequency of generation of action potentials is an indication of the degree of sustained depolarization at the axon hillock.
- Neuromodulators can alter either the rate of neurotransmitter release or the response of a postsynaptic neuron to specific neurotransmitters.
- Neurons may be facilitated or inhibited by extracellular chemicals other than neurotransmitters or neuromodulators.
- The response of a postsynaptic neuron to the activation of a presynaptic neuron can be altered by (1) the presence of neuromodulators or other chemicals that cause facilitation or inhibition at the synapse, (2) activity under way at other synapses affecting the postsynaptic cell, and (3) modification of the rate of neurotransmitter release through presynaptic facilitation or presynaptic inhibition.

Table 12-5 summarizes the basic principles of information processing.

You are now familiar with the basic components of nervous tissue, and the origin and significance of action potentials. In the next four chapters, we consider higher levels of anatomical and functional organization within the nervous system, examine information processing at these levels, and learn how a single process—the generation of action potentials—can be responsible for the incredible diversity of sensations and movements that one experiences each day.

✓ Checkpoint

25. **One EPSP depolarizes the initial segment from a resting membrane potential of -70 mV to -65 mV, and threshold is at -60 mV. Will an action potential be generated?**
26. **Given the situation in Checkpoint Question 25, if a second, identical EPSP occurs immediately after the first, will an action potential be generated?**
27. **If the two EPSPs in Checkpoint Question 26 occurred at the same time, what form of summation would occur?**

See the blue Answers tab at the back of the book.

12 Chapter Review

Study Outline

An Introduction to the Nervous System and Nervous Tissue

1. The nervous system includes all the nervous tissue in the body. The basic functional unit is the **neuron**.

12-1 The nervous system has anatomical and functional divisions

2. The anatomical divisions of the nervous system are the **central nervous system (CNS)** (the brain and spinal cord) and the

Media Resources:

- Chapter Quizzes, Chapter Practice Test, MP3 Tutor Sessions, and Clinical Case Studies
- Practice Anatomy Lab
- Interactive Physiology
- A&P Flix
- PhysioEx

peripheral nervous system (PNS) (all the nervous tissue outside the CNS and ENS). The subdivisions of the PNS are the *somatic nervous system* and the *autonomic nervous system*. Bundles of **axons** (*nerve fibers*) in the PNS are called **nerves**. (Figure 12-1)

3. Functionally, the PNS can be divided into an **afferent division**, which brings sensory information from **receptors** to the CNS, and an **efferent division**, which carries motor commands to muscles and glands called **effectors**. (Figure 12-1)
4. The efferent division of the PNS includes the **somatic nervous system (SNS)**, which controls skeletal muscle contractions, and the **autonomic nervous system (ANS)**, which controls smooth muscle, cardiac muscle, glandular activity, and adipose tissue. The ANS also includes the *enteric nervous system* (ENS), which can function independently from the CNS to control reflexes of the gastrointestinal tract. (Figure 12-1)

12-2 Neurons are nerve cells specialized for intercellular communication

5. The **perikaryon** of a multipolar neuron surrounds the nucleus and contains organelles, including **neurofilaments**, **neurotubules**, and **neurofibrils**. The **axon hillock** connects the **initial segment** of the **axon** to the **cell body**, or *soma*. The **axoplasm** contains numerous organelles. (Figure 12-2)
6. **Collaterals** may branch from an axon, with **telodendria** branching from the axon's tip.
7. Neurons are structurally classified as **anaxonic**, **bipolar**, **unipolar**, or **multipolar**. (Figure 12-3)
8. The three functional categories of neurons are sensory neurons, motor neurons, and interneurons.
9. **Sensory neurons**, which form the afferent division of the PNS, deliver information received from **interoceptors**, **exteroceptors**, and **proprioceptors** to the CNS.
10. **Motor neurons**, which form the efferent division of the PNS, stimulate or modify the activity of a peripheral tissue, organ, or organ system.
11. **Interneurons** (*association neurons*) are always located in the CNS and may be situated between sensory and motor neurons. They distribute sensory inputs and coordinate motor outputs.

12-3 CNS and PNS neuroglia support and protect neurons

12. The four types of **neuroglia**, or *glial cells*, in the CNS are (1) **astrocytes**, the largest and most numerous neuroglia; (2) **ependymal cells**, with functions related to the **cerebrospinal fluid (CSF)**; (3) **oligodendrocytes**, which are responsible for the **myelination** of CNS axons; and (4) **microglia**, or phagocytic cells. (Figures 12-4, 12-5)
13. Neuron cell bodies in the PNS are clustered into **ganglia**.
14. **Satellite cells** surround neuron cell bodies within ganglia. **Schwann cells** cover axons in the PNS. A single Schwann cell may myelinate one segment of an axon or enclose segments of several unmyelinated axons. (Figure 12-6)
15. In the PNS, functional repair of axons may follow **Wallerian degeneration**. In the CNS, many factors complicate the repair process and reduce the chances of functional recovery. (Figure 12-7)

12-4 The membrane potential of a neuron is determined by differences in ion concentrations and membrane permeability

16. All normal neural signals depend on events that occur at the plasma membrane. (Spotlight Figure 12-8)

17. The **electrochemical gradient** is the sum of all chemical and electrical forces acting across the plasma membrane. (Figure 12-9)
18. The sodium-potassium exchange pump stabilizes the resting membrane potential at approximately -70 mV. (Table 12-1)
19. The plasma membrane contains **passive (leak) ion channels**, which are always open, and **active (gated) ion channels**, which open or close in response to specific stimuli. (Figures 12-9, 12-10)
20. The three types of gated channels are **chemically gated ion channels (ligand-gated ion channels)**, **voltage-gated ion channels**, and **mechanically gated ion channels**. (Figure 12-10)
21. A localized **depolarization** or **hyperpolarization** is a **graded potential** (a change in potential that decreases with distance). (Figures 12-11, 12-12; Table 12-2)

12-5 An action potential is an all-or-none electrical event used for long-distance communication

22. An **action potential** arises when a region of excitable membrane depolarizes to its **threshold**. The steps involved, in order, are membrane depolarization to threshold, activation of voltage-gated sodium ion channels and rapid depolarization, inactivation of voltage-gated sodium ion channels and activation of voltage-gated potassium ion channels, and the return to normal permeability. (Spotlight Figure 12-13; Table 12-3)
23. The generation of an action potential follows the **all-or-none principle**. The **refractory period** lasts from the time an action potential begins until the normal resting membrane potential has returned. (Spotlight Figure 12-13; Table 12-3)
24. In **continuous propagation**, an action potential spreads across the entire excitable membrane surface in a series of small steps. (Spotlight Figure 12-14)
25. In **saltatory propagation**, an action potential appears to leap from node to node, skipping the intervening myelinated membrane surface. Saltatory propagation carries nerve impulses many times more rapidly than does continuous propagation. (Spotlight Figure 12-14)
26. Axons are classified as **Type A fibers**, **Type B fibers**, or **Type C fibers** on the basis of their diameter, myelination, and propagation speed.

12-6 Synapses transmit signals among neurons or between neurons and other cells

27. A **synapse** is a site of intercellular communication. At a synapse between two neurons, information passes from the **presynaptic neuron** to the **postsynaptic neuron**.
28. **Neurotransmitters** released from the axon terminals of the presynaptic cell affect the postsynaptic cell, which may be a neuron or another type of cell. (Figures 12-2, 12-15)
29. A synapse is either *electrical* (with direct physical contact between cells) or *chemical* (involving a neurotransmitter).
30. **Electrical synapses** occur in the CNS and PNS, but they are rare. At an electrical synapse, the presynaptic and postsynaptic plasma membranes are bound by interlocking membrane proteins at a gap junction. Pores formed by these proteins permit the passage of local currents, and the two neurons act as if they share a common plasma membrane.
31. **Chemical synapses** are far more common than electrical synapses. **Cholinergic synapses** release the neurotransmitter **acetylcholine (ACh)**. Communication moves from the presynaptic neuron to the postsynaptic neuron across a synaptic cleft. A **synaptic delay** occurs because calcium ion influx and the release of the neurotransmitter take an appreciable length of time. (Figure 12-16)

32. **Choline** released during the breakdown of ACh in the synaptic cleft is reabsorbed and recycled by the axon terminal. If stores of ACh are exhausted, **synaptic fatigue** can occur.

12-7 The effects of neurotransmitters and neuromodulators depend on their receptors

33. **Excitatory neurotransmitters** cause depolarization and promote the generation of action potentials, whereas **inhibitory neurotransmitters** cause hyperpolarization and suppress the generation of action potentials.
34. The effect of a neurotransmitter on the postsynaptic membrane depends on the properties of the receptor, not on the nature of the neurotransmitter.
35. **Adrenergic synapses** release **norepinephrine (NE)**, also called *noradrenaline*. Other important neurotransmitters include **dopamine**, **serotonin**, and **gamma aminobutyric acid (GABA)**.
36. **Neuromodulators** influence the postsynaptic cell's response to neurotransmitters. (Table 12-4)
37. Neurotransmitters can have a direct effect on membrane potential, an indirect effect on membrane potential through G proteins, or, if lipid-soluble gases, an indirect effect through intracellular enzymes (Figure 12-17)

12-8 Individual neurons process information by integrating excitatory and inhibitory stimuli

38. Excitatory and inhibitory stimuli are integrated through interactions between **postsynaptic potentials**. This interaction is the simplest level of **information processing** in the nervous system.
39. A depolarization caused by a neurotransmitter is an **excitatory postsynaptic potential (EPSP)**. Individual EPSPs can combine through **summation**, which can be either **temporal** (occurring at a single synapse when a second EPSP arrives before the effects of the first have disappeared) or **spatial**

(resulting from the cumulative effects of multiple synapses at various locations). (Figure 12-18)

40. Hyperpolarization of the postsynaptic membrane is an **inhibitory postsynaptic potential (IPSP)**.
41. The most important determinants of neural activity are EPSP-IPSP interactions. (Figure 12-19)
42. In **presynaptic inhibition**, GABA release at an *axoaxonic synapse* inhibits the opening of voltage-gated calcium ion channels in the axon terminal. This inhibition reduces the amount of neurotransmitter released when an action potential arrives at the axon terminal. (Figure 12-20a)
43. In **presynaptic facilitation**, activity at an axoaxonic synapse increases the amount of neurotransmitter released when an action potential arrives at the axon terminal. This increase enhances and prolongs the effects of the neurotransmitter on the postsynaptic membrane. (Figure 12-20b)
44. The neurotransmitters released at a synapse have excitatory or inhibitory effects. The effect on the initial segment reflects an integration of the stimuli arriving at any moment. The frequency of generation of action potentials depends on the degree of depolarization above threshold at the axon hillock. (Table 12-5)
45. Neuromodulators can alter either the rate of neurotransmitter release or the response of a postsynaptic neuron to specific neurotransmitters. Neurons may be facilitated or inhibited by extracellular chemicals other than neurotransmitters or neuromodulators. (Table 12-5)
46. The effect of a presynaptic neuron's activation on a postsynaptic neuron may be altered by other neurons. (Table 12-5)
47. The greater the degree of sustained depolarization at the axon hillock, the higher the frequency of generation of action potentials. At a frequency of about 1000 per second, the relative refractory period has been eliminated, and further depolarization will have no effect. (Table 12-5)

Review Questions

See the blue Answers tab at the back of the book.

LEVEL 1 Reviewing Facts and Terms

1. Label the structures in the following diagram of a neuron.

- | | |
|-----------|-----------|
| (a) _____ | (b) _____ |
| (c) _____ | (d) _____ |
| (e) _____ | (f) _____ |
| (g) _____ | (h) _____ |
| (i) _____ | |

2. Regulation by the nervous system provides (a) relatively slow, but long-lasting, responses to stimuli, (b) swift, long-lasting responses to stimuli, (c) swift, but brief, responses to stimuli, (d) relatively slow, short-lived responses to stimuli.
3. Which effectors are *not* controlled by the ANS? (a) skeletal muscles, (b) heart muscles, (c) smooth muscles, (d) glands.
4. The somatic motor neurons control the activity of the (a) cardiac muscles, (b) smooth muscles, (c) skeletal muscles, (d) glands.
5. The cell type that creates the blood brain barrier is the (a) microglial cell, (b) ependymal cell, (c) astrocyte, (d) oligodendrocyte.
6. Depolarization of a neuron plasma membrane will shift the membrane potential toward (a) 0 mV, (b) -70 mV, (c) -90 mV, (d) all of these.
7. What factor determines the direction that ions will move through an open membrane channel? (a) the membrane permeability to sodium ions, (b) the electrochemical gradient, (c) intracellular negatively charged proteins, (d) negatively charged chloride ions in the ECF.

8. Endorphins play an important role in **(a)** stimulating food intake, **(b)** controlling pain, **(c)** memory and learning, **(d)** regulating subconscious motor function.
9. What are the major components of **(a)** the central nervous system? **(b)** the peripheral nervous system? **(c)** the enteric nervous system?
10. Name two medical conditions characterized by destruction of the myelin sheath.
11. Which are the three types of sensory receptors in the afferent division of the PNS? What is the function of each?

LEVEL 2 Reviewing Concepts

12. If the resting membrane potential of a neuron is -70 mV and the threshold is -55 mV, a membrane potential of -60 mV will **(a)** produce an action potential, **(b)** make it easier to produce an action potential, **(c)** make it harder to produce an action potential, **(d)** hyperpolarize the membrane.
13. How can you distinguish between an anaxonic neuron and a multipolar neuron?
14. What is the difference between interoceptors and proprioceptors?
15. What is the *functional* difference among chemically gated (ligand-gated), voltage-gated, and mechanically gated ion channels?
16. What is the difference between absolute and relative refractory periods?
17. Describe the events that occur during peripheral nerve regeneration after injury.
18. What is meant by saltatory propagation? How does it differ from continuous propagation?
19. What is the difference between an electrical synapse and a chemical synapse?
20. Describe the events that occur during nerve impulse transmission at a typical cholinergic synapse.
21. What is the difference between presynaptic inhibition and presynaptic facilitation?

LEVEL 3 Critical Thinking and Clinical Applications

22. Manny has a kidney condition that causes changes in his body's electrolyte levels (concentration of ions in the extracellular fluid). As a result, he is exhibiting tachycardia, an abnormally fast heart rate. Which ion is involved, and how does a change in its concentration cause Manny's symptoms?
23. Twenty neurons synapse with a single receptor neuron. Fifteen of the 20 neurons release neurotransmitters that produce EPSPs at the postsynaptic membrane, and the other 5 release neurotransmitters that produce IPSPs. Each time one of the neurons is stimulated, it releases enough neurotransmitter to produce a 2 mV change in potential at the postsynaptic membrane. If the threshold of the postsynaptic neuron is 10 mV, how many of the excitatory neurons must be stimulated to produce an action potential in the receptor neuron if all 5 inhibitory neurons are stimulated? (Assume that spatial summation occurs.)
24. A man is bitten by a rabid dog. His doctor warns him about the seriousness of the event but adds that it should not be fatal if treated correctly. What happens in rabies on the neural level?
25. What factor determines the maximum frequency of action potentials that could be propagated by an axon?

CLINICAL CASE Wrap-Up Did President Franklin D. Roosevelt Really Have Polio?

Poliomyelitis is caused by a virus that spreads easily in human populations. Most people with polio infections show no signs of disease. However, in a small percentage of victims, the virus enters the central nervous system, attacks the motor neurons of the spinal cord, and produces a flaccid paralysis (characterized by weakness and loss of muscle tone).

Certain details about Mr. Roosevelt's case call into question whether he really had polio. Polio is a disease primarily of children. By age 30, most adults have naturally acquired immunity, a resistance to infection developed after a previous exposure. In addition, paralysis caused by polio is usually asymmetric, does not appear in an ascending pattern, and progresses for only 3 to 5 days—not for nearly a month, as in Mr. Roosevelt's case. Polio almost never involves facial muscles or disturbs urinary bladder and bowel functions. Polio also does not cause pain upon light touch, other pain, or numbness—only motor weakness. Mr. Roosevelt recovered from his paralysis in a descending pattern, opposite to its onset.

The pathological features Mr. Roosevelt experienced are much more characteristic of Guillain-Barré (GĒ -yan bah-RĀ) syndrome, an autoimmune disease that involves the demyelination (destruction of the axonal myelin sheath) of peripheral nerves. It causes symmetrical weakness, numbness, and abnormal sensations. In the first half of the 20th century, doctors had extensive experience with polio, but knew little about Guillain-Barré syndrome.

While it is still inconclusive which condition led to the lifetime impairment of our 32nd president, Franklin D. Roosevelt's polio diagnosis ultimately contributed to ending polio. In fact, a current goal of the Bill & Melinda Gates Foundation is to eradicate polio worldwide.

1. Which cells of the CNS are targeted by the polio virus?
2. If Mr. Roosevelt had Guillain-Barré syndrome, where in his nervous system was the pathology taking place?

See the blue Answers tab at the back of the book.

Related Clinical Terms

anesthetic: An agent that produces a local or general loss of sensation including feelings of pain.

anticholinesterase drug: A drug that blocks the breakdown of ACh by AChE.

atropine: A drug that prevents ACh from binding to the postsynaptic membrane of cardiac muscle cells and smooth muscle cells.

d-tubocurarine: A drug, derived from curare, a South American rain forest vine. It produces paralysis by preventing ACh from binding to the postsynaptic membrane (motor end plate) of skeletal muscle fibers.

dysthymia: A form of clinical depression with a depressed mood for most of the time for at least 2 years along with at least two of the following signs and symptoms: poor appetite or overeating, insomnia or excessive sleep, low energy or fatigue, low self-esteem, poor concentration or indecisiveness, and hopelessness.

excitotoxicity: Continuous and exaggerated stimulation by a neurotransmitter, especially for the excitatory neurotransmitter glutamate. The nerve cells can become damaged and killed by the overactivation of receptors.

neuroblastoma: A malignant tumor composed of neuroblasts, most commonly in the adrenal gland; it is the most common cancer in infancy.

neuropathy: Condition that causes tingling, numbness, and/or pain in parts of the body, notably the hands and feet.

neurotoxin: A compound that disrupts normal nervous system function by interfering with the generation or propagation of action potentials. Examples include *tetrodotoxin* (TTX), *saxitoxin* (STX), and *ciguatoxin* (CTX).

Tay–Sachs disease: A genetic abnormality involving the metabolism of gangliosides, important lipid components of neuron plasma membranes. The result is a gradual deterioration of neurons due to the buildup of metabolic by-products and the release of lysosomal enzymes.

13

The Spinal Cord, Spinal Nerves, and Spinal Reflexes

Learning Outcomes

These Learning Outcomes correspond by number to this chapter's sections and indicate what you should be able to do after completing the chapter.

- 13-1 ■ Describe the basic structural and organizational characteristics of the nervous system.
- 13-2 ■ Discuss the structure and functions of the spinal cord and describe the three meningeal layers that surround the central nervous system.
- 13-3 ■ Explain the roles of white matter and gray matter in processing and relaying sensory information and motor commands.
- 13-4 ■ Describe the major components of a spinal nerve, describe a nerve plexus, and relate the distribution pattern of spinal nerves to the regions they innervate.
- 13-5 ■ Discuss the significance of neuronal pools and describe the major patterns of interaction among neurons within and among these pools.
- 13-6 ■ Describe the steps in a neural reflex and classify the types of reflexes.
- 13-7 ■ Distinguish among the types of motor responses produced by various reflexes and explain how reflexes interact to produce complex behaviors.
- 13-8 ■ Explain how higher brain centers control and modify reflex responses.

CLINICAL CASE Prom Night

Grady is still buzzing from champagne as he kisses his girlfriend goodnight and gets into his car to head home. It's been a fun prom. The food was great, the band was awesome, and the afterparty at his friend's house had gone until 3 a.m. Grady pulls the car onto the road, turns the stereo to full blast, and steps on the gas pedal. Then, suddenly tired, he leans back and notices the moon through the trees. That is the last thing he remembers.

The emergency medical technicians (EMTs) at the motor vehicle accident scene note that Grady's car had left the road, probably at a high rate of speed, and rolled over at least three times. Grady is still unconscious when he is removed from the car. He is breathing on his own but has obvious abrasions and bruising on his back. The EMTs splint his

entire axial skeleton, using a cervical collar and sandbags on a rigid backboard. They start an IV and transport Grady to the closest Level I trauma center.

In the emergency department Grady can hear shouting in his ear as he is moved onto a cart. "Wiggle your toes," someone commands, but Grady can move nothing below his waist. "Can you feel this?" a voice asks. Grady can feel someone poking him with a pin from his chest down to his abdomen, just inferior to his

navel, but nothing below that. "Can you feel me put this catheter in?" a nurse asks as she inserts a small tube into Grady's bladder. Grady cannot feel the catheter. **What has happened to Grady? To find out, turn to the Clinical Case Wrap-Up at the end of the chapter.**

13

An Introduction to the Spinal Cord, Spinal Nerves, and Spinal Reflexes

Organization is usually the key to success in any complex environment. A large corporation, for example, has both a system to distribute messages on specific topics and executive assistants who decide whether an issue can be ignored or easily responded to. Only the most complex and important problems reach the desk of the president.

The nervous system works in much the same way. It has input pathways that route sensations and processing centers that prioritize and distribute information. There are also several levels that issue motor responses. The conscious mind (the president) gets involved only in a fraction of the day-to-day activities. The other decisions are handled at lower "management" levels, such as the spinal cord, that operate outside our awareness. This very efficient system works only because it is so highly organized.

In this chapter, we discuss the functional anatomy and organization of the spinal cord and spinal nerves. We also describe simple spinal reflexes.

13-1 This text's coverage of the nervous system parallels its simple-to-complex levels of organization

Learning Outcome Describe the basic structural and organizational characteristics of the nervous system.

The nervous system has so many components and does so much that we cover it in several chapters. If our primary interest were the anatomy of the nervous system, we would probably start with an examination of the **central nervous system** (brain and spinal cord) and then move on to the **peripheral**

nervous system (cranial nerves and spinal nerves). However, our primary interest is how the nervous system *functions*, so we consider the system from a functional perspective. Our basic approach for Chapters 13 and 14 is diagrammed in **Figure 13-1**.

Recall that Chapter 12 considered the function of individual neurons. In this chapter, we consider the spinal cord and spinal nerves, the basics of neural reflexes, and simple spinal reflexes. *Reflexes* are quick, automatic responses triggered by specific stimuli. *Spinal reflexes* are controlled in the spinal cord. They function without any input from the brain. For example, a reflex controlled in the spinal cord makes a person drop a frying pan they didn't realize was sizzling hot. Before the information reaches their brain and they become aware of the pain, the person has already released the pan. More complex spinal reflexes exist, but this functional pattern still applies.

The spinal cord is structurally and functionally integrated with the brain. In Chapter 14 we give an overview of the major structures and functions of the brain and cranial nerves. We also discuss *cranial reflexes*—localized reflex responses comparable to those of the spinal cord.

In Chapters 15 and 16 we consider the nervous system as an integrated functional unit. In Chapter 15 we deal with the interplay between the brain and spinal cord that occurs when processing sensory information. We then examine the conscious and subconscious control of skeletal muscles by the *somatic nervous system* (SNS).

In Chapter 16 we continue with a discussion of visceral functions by the *autonomic nervous system* (ANS). The ANS has processing centers in the brain, spinal cord, and peripheral nervous system. It controls visceral effectors, such as smooth muscles, cardiac muscle, glands, and adipose tissue. We conclude that chapter by examining *higher-order functions*: memory, learning, consciousness, and personality. These topics are

Figure 13–1 An Overview of Chapters 13 and 14.

difficult to investigate, but they affect activity along the sensory and motor pathways and alter our perception of those activities.

With these basic principles, definitions, and strategies in mind, let's begin our examination of the functional organization in the nervous system.

✓ Checkpoint

1. Name the structures of the central nervous system (CNS) and of the peripheral nervous system (PNS).
2. Define spinal reflex.

See the blue Answers tab at the back of the book.

13-2 The spinal cord is surrounded by three meninges and has spinal nerve roots

Learning Outcome Discuss the structure and functions of the spinal cord and describe the three meningeal layers that surround the central nervous system.

The **spinal cord** is an organ primarily made up of nervous tissue that is found within protective membranes and the bony vertebral column. This organ carries sensory and motor

information between the brain and most other parts of the body. To carry out this function, the spinal cord is the origin of many *spinal nerves*, which allow communication with the peripheral organs. This section focuses on the anatomy of the spinal cord and its protection, while we cover spinal cord function in Section 13–3. We begin this section with the gross and cross-sectional anatomy of the spinal cord. Then we examine the three membranous layers that surround the spinal cord: the *spinal meninges* (meh-NIN-jēz).

Gross Anatomy of the Spinal Cord

The adult spinal cord (**Figure 13–2a**) is approximately 45cm (18in.) long, with a maximum width of about 14 mm (0.55in.). Note that the cord itself is not as long as the vertebral column. Instead, the adult spinal cord extends inferiorly from the brain and ends between vertebrae L₁ and L₂. Like the vertebrae, there are four spinal cord regions: *cervical*, *thoracic*, *lumbar*, and *sacral*. The spinal cord contains both gray matter (primarily made up of neuron cell bodies) and white matter (primarily myelinated axons). **Figure 13–2b** shows a lateral view, and **Figure 13–2c** is a series of cross-sectional views that illustrate the variations in the proportions of gray matter and white matter in the various regions of the spinal cord.

Figure 13-2 Gross Anatomy of the Adult Spinal Cord.

The entire spinal cord is divided into 31 segments based on the origins of the spinal nerves. A letter and number designation, the same method used to identify vertebrae, identifies each segment. For example, C₃, the spinal segment in the uppermost section of **Figure 13-2c**, is the third cervical segment.

The posterior (dorsal) surface of the spinal cord has a shallow longitudinal groove, the **posterior median sulcus**. The **anterior median fissure** is a deeper groove along the anterior (ventral) surface. In addition, the spinal cord has an internal passageway called the **central canal**. As noted in Chapter 12, this space is filled with **cerebrospinal fluid (CSF)**, which acts as a shock absorber and a medium for the diffusion of dissolved gases, nutrients, chemical messengers, and wastes.

The amount of gray matter is greatest in segments of the spinal cord dedicated to the sensory and motor control of the limbs. These segments are expanded, forming two **enlargements** of the spinal cord. The **cervical enlargement** supplies nerves to the shoulder and upper limbs. The **lumbosacral enlargement** innervates structures of the pelvis and lower limbs.

Inferior to the lumbosacral enlargement, the spinal cord becomes tapered and conical. This region is the **conus medullaris** (med-yū-LAR-us). The **filum terminale** (FĪ-lum ter-mi-NAH-lā; “terminal thread”), a slender strand of fibrous tissue, extends from the inferior tip of the conus medullaris. It continues along the length of the vertebral canal as far as the second sacral vertebra, where it longitudinally supports the spinal cord as a part of the *coccygeal ligament*.

Spinal Roots and Ganglia

Every spinal segment is associated with a pair of **spinal ganglia** (*posterior root ganglia*) located near the spinal cord (**Figure 13-2c**). These ganglia contain the cell bodies of sensory neurons. The axons of the neurons form the **posterior roots** or **dorsal roots**, which bring sensory information into the spinal cord. A pair of **anterior roots**, or **ventral roots**, contains the axons of motor neurons that extend into the periphery to control somatic and visceral effectors. The roots of all spinal nerves divide in fanlike fashion, forming **rootlets**, before entering or leaving the spinal cord. A spinal posterior root may divide into 8–12 rootlets (**Figure 13-3a**).

On both sides, the posterior and anterior roots of each segment pass between the vertebral canal and the periphery at the *intervertebral foramen* between successive vertebrae. The spinal ganglion lies between the pedicles of the adjacent vertebrae.

The spinal cord continues to enlarge and elongate until approximately 4 years of age. Up to that time, enlargement of the spinal cord keeps pace with the growth of the vertebral column. Throughout this time, the posterior and anterior roots are very short, and they enter the intervertebral foramina immediately adjacent to their spinal segment. After age 4, the vertebral column continues to elongate, but the spinal cord does not.

Figure 13-3 The Spinal Cord and Spinal Meninges.

a A posterior view of the spinal cord, showing the meningeal layers, superficial landmarks, and distribution of gray matter and white matter

b A sectional view through the spinal cord and meninges, showing the relationship of the meninges, spinal cord, and spinal nerves

What is the area between the arachnoid mater and the pia mater?

This vertebral growth moves the intervertebral foramina and thus the spinal nerves farther and farther from their original positions relative to the spinal cord. As a result, the posterior and anterior roots gradually elongate, and the correspondence between the spinal segment and the vertebral segment is lost. For example, in adults, the sacral segments of the spinal cord are at the level of vertebrae L_1 – L_2 (**Figure 13–2**).

In adults the posterior and anterior roots of spinal segments L_2 to S_5 extend inferiorly, past the inferior tip of the conus medullaris. When seen in gross dissection, the filum terminale and the long anterior and posterior roots resemble a horse's tail. For this reason, early anatomists called this complex the **cauda equina** (KAW-duh ek-WĪ-nuh; *cauda*, tail + *equus*, horse).

Spinal Nerves and Rami (Branches)

Distal to each spinal ganglion, the sensory and motor roots are bound together into a single **spinal nerve** just lateral to the intervertebral foramen. The spinal nerve then forms branches containing nerve fibers that carry sensory and/or motor information. These branches include paired communicating structures called *rami communicantes* (singular, *ramus communicans*), a posterior ramus, and an anterior ramus (**Figure 13–3b**). A typical spinal nerve has a **white ramus communicans** (containing myelinated axons), a **gray ramus communicans** (containing unmyelinated fibers that innervate glands and smooth muscles in the body wall or limbs), a **posterior ramus** (providing sensory and motor innervation to the skin and muscles of the back), and an **anterior ramus** (supplying the ventrolateral body surface, structures in the body wall, and the limbs).

Spinal nerves are classified as *mixed nerves*—that is, they contain both afferent (sensory) and efferent (motor) fibers. As mentioned, there are 31 pairs of spinal nerves, each identified by its association with adjacent vertebrae. For example, we speak of “cervical spinal nerves” or even “cervical nerves” when we make a general reference to spinal nerves of the neck.

However, when we indicate specific spinal nerves, it is customary to give them a regional number, as indicated in **Figure 13–2**. In the cervical region, the first pair of spinal nerves, C_1 , passes between the skull and the first cervical vertebra. For this reason, each cervical nerve takes its name from the vertebra immediately *inferior* to it. In other words, cervical nerve C_2 comes before vertebra C_2 , and the same system is used for the rest of the cervical series. However, the spinal nerve found between the last cervical vertebra and first thoracic vertebra has been designated C_8 . Therefore, although there are only seven cervical vertebrae, there are *eight* pairs of cervical nerves. Then each spinal nerve inferior to the first thoracic vertebra (down through the lumbar and sacral vertebrae) takes its name from the vertebra immediately *superior* to it. For example, spinal nerve T_1 emerges immediately inferior to vertebra T_1 , spinal nerve T_2 follows vertebra T_2 , and so forth.

Protection of the Spinal Cord: Spinal Meninges

The vertebral column and its surrounding ligaments, tendons, and muscles isolate the spinal cord from the rest of the body. These structures also protect against bumps and shocks to the back. The delicate neural tissues must also be protected from damaging contacts with the surrounding bony walls of the vertebral canal. The **spinal meninges** (me-NIN-jēz), a series of specialized membranes surrounding the spinal cord, provide the necessary physical stability and shock absorption. In addition, blood vessels branching within these layers deliver oxygen and nutrients to the spinal cord.

The spinal meninges consist of three layers: (1) the *dura mater*, (2) the *arachnoid mater*, and (3) the *pia mater*. The relationships among these membranes are shown in **Figure 13–3**. At the foramen magnum of the skull, the spinal meninges are continuous with the **cranial meninges**, which surround the brain. (The cranial meninges have the same three layers. We discuss them in Chapter 14.)

The Dura Mater

The tough, fibrous **dura mater** (DŪ-ruh MĀ-ter; *durus*, hard + *mater*, mother) is the layer that forms the outermost covering of the spinal cord (**Figure 13–3a**). This layer contains dense collagen fibers that are oriented along the longitudinal axis of the cord. Between the dura mater and the walls of the vertebral canal lies the **epidural space**, a region that contains areolar tissue, blood vessels, and a protective padding of adipose tissue (**Figure 13–3b**).

The connections of the spinal dura mater to its bony surroundings vary. The outer layer of the spinal dura mater fuses with the periosteum of the occipital bone of the cranium around the margins of the foramen magnum. There, the spinal dura mater becomes continuous with the cranial dura mater. However, the spinal dura mater does not have extensive, firm connections to the surrounding vertebrae. Attachment sites at either end of the vertebral canal provide longitudinal stability. In addition, the dura mater extends between adjacent vertebrae at each intervertebral foramen, fusing with the connective tissues that surround the spinal nerves. Within the sacral canal on the posterior surface of the sacrum, the spinal dura mater tapers from a sheath to a dense cord of collagen fibers that blends with components of the filum terminale to form the **coccygeal ligament** (**Figure 13–2a**). The coccygeal ligament continues along the sacral canal, ultimately blending into the periosteum of the coccyx.

The Arachnoid Mater

In most anatomical and tissue specimens, a narrow **subdural space** separates the dura mater from deeper meningeal layers. In a healthy living individual no such space exists. Instead, the inner surface of the dura mater is in contact with the outer surface of the **arachnoid** (a-RAK-noyd; *arachne*, spider) **mater**,

the middle meningeal layer (**Figure 13-3b**). The inner surface of the dura mater and the outer surface of the arachnoid mater are covered by simple squamous epithelia. The arachnoid mater includes this epithelium, called the *arachnoid membrane*, and the *arachnoid trabeculae*, a delicate network of collagen and elastic fibers that extends between the arachnoid membrane and the outer surface of the pia mater. The region between is called the **subarachnoid space**, and it is filled with CSF.

The spinal arachnoid mater extends inferiorly as far as the filum terminale, and the posterior and anterior roots of the cauda equina lie within the fluid-filled subarachnoid space. In adults, the withdrawal of CSF involves the insertion of a needle into the subarachnoid space in the inferior lumbar region. This procedure is known as a **lumbar puncture**, or **spinal tap**.

The Pia Mater

The subarachnoid space extends between the arachnoid epithelium and the innermost meningeal layer, the **pia mater** (PĒ-uh; *pia*, delicate + *mater*, mother). The pia mater consists of a meshwork of elastic and collagen fibers that is firmly bound to the underlying neural tissue (**Figure 13-3**). These connective tissue fibers are interwoven with those that span the subarachnoid space, firmly binding the arachnoid to the pia mater. The blood vessels servicing the spinal cord run along the surface of the spinal pia mater, within the subarachnoid space (**Figure 13-4**).

Along the length of the spinal cord, paired **denticulate ligaments** extend from the pia mater through the arachnoid mater to the dura mater (**Figures 13-3b, 13-4**). Denticulate ligaments, which originate along either side of the spinal cord, prevent lateral (side-to-side) movement. The dural connections at the foramen magnum and the coccygeal ligament prevent longitudinal (superior-inferior) movement.

The spinal meninges accompany the posterior and anterior roots as these roots pass through the intervertebral foramina.

Figure 13-4 The Spinal Cord and Associated Structures.

An anterior view of the cervical spinal cord and spinal nerve roots in the vertebral canal. The dura mater and arachnoid mater have been cut and reflected. Notice the blood vessels that run in the subarachnoid space, bound to the outer surface of the delicate pia mater.

As the sectional view in **Figure 13-3b** shows, the meningeal membranes are continuous with the connective tissues that surround the spinal nerves and their peripheral branches.

Bacterial or viral infection can cause **meningitis**, or inflammation of the meningeal membranes. Meningitis is dangerous because it can disrupt the normal circulation of CSF, damaging

Clinical Note Anesthesia

Anesthetics are often injected into the epidural space. Introduced in this way, a drug should affect only the spinal nerves in the immediate area of the injection. The result is a regional pain reliever (analgesic) called *epidural anesthesia*, which blocks pain sensations.

This procedure can be done either peripherally, as when skin lacerations are sewn up, or at sites around the spinal cord for more widespread anesthetic effects, as during labor and delivery. An epidural anesthetic has at least two advantages: (1) It affects only the spinal nerves in the immediate area of the injection, and (2) it provides mainly sensory anesthesia.

Local anesthetics can also be introduced as a single dose into the subarachnoid space of the spinal cord. This procedure is commonly called **spinal anesthesia**. The effects

include both temporary muscle paralysis and sensory loss. These effects tend to spread as the movement of cerebrospinal fluid distributes the anesthetic along the spinal cord. Problems with overdosing are seldom serious, because controlling the patient's position during administration can limit the distribution of the drug. Breathing continues even if all thoracic and abdominal segments have been paralyzed because the upper cervical spinal nerves control the diaphragm.

In the United States, anesthesia is often administered by a certified registered nurse anesthetist (CRNA). Nurse anesthetists are highly skilled, advanced practice registered nurses with graduate-level degrees. All CRNAs have been educated in an accredited nurse anesthesia program and have passed a national certification examination.

or killing neurons and neuroglia in the affected areas. An initial diagnosis may locate the infection in the meninges of the spinal cord (*spinal meningitis*) or brain (*cerebral meningitis*), but in later stages the entire meningeal system is usually affected.

3. Identify the three spinal meninges.
4. Damage to which root of a spinal nerve would interfere with motor function?
5. Where is the cerebrospinal fluid that surrounds the spinal cord located?

See the blue Answers tab at the back of the book.

13-3 Spinal cord gray matter integrates information and initiates commands, and white matter carries information from place to place

13 Learning Outcome Explain the roles of white matter and gray matter in processing and relaying sensory information and motor commands.

Note that the patterns of gray and white matter found in cross sections of the spinal cord vary with the spinal cord regions (**Figure 13-2c**). Recall that in nervous tissue **gray matter** is dominated by the cell bodies of neurons, neuroglia, and unmyelinated axons, while the **white matter** contains large numbers of myelinated and unmyelinated axons. In this section we relate this cross-sectional, structural organization to the functional organization of both gray and white matter in the spinal cord (**Figure 13-5**).

Functional Organization of Gray Matter

The left side of **Figure 13-5a** shows the structural pattern of gray matter in the spinal cord. In cross section, this gray matter forms an H, or butterfly, shape and surrounds the narrow central canal. The areas of gray matter on each side of the spinal cord (to the left or right halves defined by the anterior median fissure and posterior median sulcus) are called **horns**. There are **posterior**, **lateral**, and **anterior horns**, depending on their positions (**Figure 13-5b**). The narrow bridges of gray matter posterior and anterior to the central canal are **gray commissures** (*commissura*, a joining together).

Now let's think about what this organization of gray matter can tell us about its function. Masses of gray matter within the CNS are called **nuclei**; there are both sensory and motor nuclei. **Sensory nuclei** receive and relay sensory information from peripheral receptors. **Motor nuclei** issue motor commands to peripheral effectors. These motor and sensory nuclei are organized together in the spinal cord. If a frontal section along the length of the central canal of the spinal cord were removed, it would separate the sensory (posterior, or dorsal)

nuclei from the motor (anterior, or ventral) nuclei. The posterior horns contain somatic and visceral sensory nuclei, and the anterior horns contain somatic motor nuclei. The lateral horns, located only in the thoracic and lumbar segments, contain visceral motor nuclei. The gray commissures contain axons that cross from one side of the cord to the other before they reach an area in the gray matter.

The right side of **Figure 13-5a** shows the relationship between the function of a particular nucleus (sensory or motor) and its position in the gray matter of the spinal cord. Although sensory and motor nuclei appear small in transverse section, nuclei are also spatially organized—they may extend for a considerable distance along the length of the spinal cord. In the cervical enlargement, for example, the anterior horns contain nuclei whose motor neurons control the muscles of the upper limbs. On each side of the spinal cord, in medial to lateral sequence, are somatic motor nuclei that control (1) muscles that position the pectoral girdle, (2) muscles that move the arm, (3) muscles that move the forearm and hand, and (4) muscles that move the hand and fingers. Within each of these regions, the motor neurons that control flexor muscles are grouped separately from those that control extensor muscles. Because the spinal cord is so highly organized, we can predict which muscles will be affected by damage to a specific area of gray matter.

Functional Organization of White Matter

How is the white matter functionally organized? Let's look at the structural organization of white matter first (look at the left side of **Figure 13-5a**). The white matter on each side of the spinal cord can be divided into three regions called **columns**. The **posterior white columns** lie between the posterior horns and the posterior median sulcus. The **anterior white columns** lie between the anterior horns and the anterior median fissure. The anterior white columns are interconnected by the **anterior white commissure**, a region where axons cross from one side of the spinal cord to the other. The white matter between the anterior and posterior columns on each side makes up the **lateral white column**.

Now let's connect the structural organization with the function of the columns. Each column contains *tracts* whose axons share functional and structural characteristics. A **tract** is a bundle of axons in the CNS that is somewhat uniform in diameter, myelination, and propagation speed. All the axons within a tract relay the same type of information (sensory or motor) in the same direction. Short tracts carry sensory or motor signals between segments of the spinal cord, and longer tracts connect the spinal cord with the brain. **Ascending tracts** carry *sensory* information toward the brain, and **descending tracts** convey *motor* commands to the spinal cord. We describe the major tracts and their functions in Chapters 15 and 16. Because spinal tracts have very specific functions, damage to one produces a characteristic loss of sensation or motor control.

Figure 13–5 The Sectional Organization of the Spinal Cord.

13-4 Spinal nerves extend to form peripheral nerves, sometimes forming plexuses along the way; these nerves carry sensory and motor information

Learning Outcome Describe the major components of a spinal nerve, describe a nerve plexus, and relate the distribution pattern of spinal nerves to the regions they innervate.

13 In this section we consider the structure and function of spinal nerves and the interwoven networks of spinal nerves called *nerve plexuses*.

Anatomy of Spinal Nerves

Every segment of the spinal cord is connected to a pair of spinal nerves. Surrounding each spinal nerve is a series of connective tissue layers continuous with those of the associated peripheral nerves (**Figure 13-6**). These wrapped layers, best seen in sectional view, are comparable to those associated with skeletal muscles. The **epineurium** (ep-ih-NŪ R-ē-um), or outermost layer, consists of a

dense network of collagen fibers. The fibers of the **perineurium**, the middle layer, extend inward from the epineurium. These connective tissue partitions divide the nerve into a series of compartments, called *fascicles*, that contain bundles of axons. Delicate connective tissue fibers of the **endoneurium**, the innermost layer, extend from the perineurium and surround individual axons.

Arteries and veins penetrate the epineurium and branch within the perineurium. Capillaries leaving the perineurium branch in the endoneurium. They supply the axons and Schwann cells of the nerve and the fibroblasts of the connective tissues.

As the spinal nerves extend into the periphery, they branch and interconnect, forming the **peripheral nerves** that innervate body tissues and organs. The connective tissue sheaths of peripheral nerves are the same as, and are continuous with, those of spinal nerves.

Recovery from an injury to a peripheral nerve may depend on the extent of the injury. If a peripheral axon is severed but not displaced, normal function may eventually return as the cut stump grows across the site of injury, away from the cell body and along its former path. Repairs made after an entire peripheral nerve has been damaged are generally incomplete, primarily due to problems with axon alignment and regrowth. Various technologically sophisticated life-changing and life-saving surgical procedures designed to improve nerve regeneration and repair are currently under evaluation.

Peripheral Distribution and Function of Spinal Nerves

A **dermatome** is the specific bilateral region of the skin surface monitored by a single pair of spinal nerves. Each pair of

Figure 13-6 A Peripheral Nerve. A diagrammatic view and an electron micrograph of a typical spinal nerve. Note the connective tissue layers that are continuous with the associated spinal nerve.

Figure 13–7 Dermatomes. Anterior and posterior distributions of dermatomes on the surface of the skin. N V = cranial nerve five (trigeminal nerve).

spinal nerves supplies its own dermatome (**Figure 13–7**). Note that the boundaries of adjacent dermatomes overlap to some degree. **Spotlight Figure 13–8** shows the distribution, or functional pathway, of a typical spinal nerve that originates from the thoracic or superior lumbar segments (T_1 – L_2) of the spinal cord. This figure considers the pathways of both the sensory information and the motor commands.

Dermatomes are clinically important because damage or infection of a spinal nerve or spinal ganglion produces a loss of

Clinical Note Shingles

The same virus that causes chickenpox, the varicella-zoster virus (VZV), also causes **shingles** (derived from the Latin *cingulum*, girdle). This virus attacks neurons within the posterior roots of spinal nerves and sensory ganglia of cranial nerves. Shingles produces a painful rash and blisters whose distribution corresponds to that of the affected sensory nerves and follows its dermatome, as shown in the photo. Treatment for shingles typically involves large doses of antiviral drugs. Fortunately for those affected, attacks of shingles usually heal, often without treatment, and leave behind only unpleasant memories.

Anyone who has had chickenpox is at risk of developing shingles. After the initial encounter, the virus remains dormant within neurons of the anterior horns of the spinal cord. It is not known what triggers the reactivation of this pathogen.

Many people who contract shingles experience just a single episode in their adult lives. Some experience a painful condition known as *postherpetic neuralgia* after a bout of shingles. Moreover, the problem can recur in those with weakened immune systems, including pregnant individuals and people with AIDS or cancer. The CDC recommends that people aged 50 and older get two doses of the shingles vaccine, Shingrix.

sensation in the corresponding region of the skin. Additionally, characteristic signs may appear on the skin supplied by that specific nerve. **Peripheral neuropathies** are regional losses of sensory and motor function most often resulting from nerve trauma or compression. (A mild, temporary version of this disorder occurs if a person has ever experienced an arm or leg “falling asleep” after leaning or sitting in an uncomfortable position.) The location of the affected dermatomes provides clues to the location of injuries along the spinal cord.

SENSORY INFORMATION

A spinal nerve collects sensory information from peripheral structures and delivers it to sensory nuclei in the thoracic or superior lumbar segments of the spinal cord. The posterior and anterior rami, and the white rami of the rami communicantes, also contain sensory fibers.

MOTOR COMMANDS

A spinal nerve distributes motor commands that originate in motor nuclei of the thoracic or superior lumbar segments of the spinal cord.

2 The spinal nerve forms just lateral to the intervertebral foramen, where the posterior and anterior roots unite.

1 The anterior root of each spinal nerve contains the axons of somatic motor and visceral motor neurons.

3 The posterior ramus contains somatic motor and visceral motor fibers that innervate the skin and skeletal muscles of the back.

4 The axons in the relatively large anterior ramus supply the ventrolateral body surface, structures in the body wall, and the limbs.

To skeletal muscles of body

Postganglionic fibers to smooth muscles, and glands of body wall, limbs

Rami communicantes

5 The white ramus communicans is the first branch from the spinal nerve and carries visceral motor fibers to a nearby sympathetic ganglion. Because these preganglionic axons are myelinated, this branch has a light color and is therefore known as the white ramus. White rami are only found between T₁ and L₂.

6 The gray ramus communicans contains postganglionic fibers that innervate glands and smooth muscles in the body wall or limbs. These fibers are unmyelinated and have a dark gray color. Gray rami are associated with each spinal nerve.

Together, the white and gray rami are known as the **rami communicantes** (RĀ-mī ko-mū-ni-KAN-tēz), or communicating branches (singular, *ramus communicans*).

Figure 13–9 Nerve Plexuses and Peripheral Nerves.

The axillary, radial, and ulnar nerves branch from which plexus?

The information, however, is not precise. More exact conclusions can be drawn if there is loss of motor control, based on the origin and distribution of the peripheral nerves originating at nerve plexuses.

Nerve Plexuses

The simple distribution pattern of posterior and anterior rami in **Spotlight Figure 13–8** applies to spinal nerves T₁–L₂. But in segments controlling the skeletal muscles of the neck, upper limbs, or lower limbs, the situation is more complicated. During development, small skeletal muscles innervated by different anterior rami typically fuse to form larger muscles with compound origins. The anatomical distinctions between the component muscles may disappear, but separate anterior rami continue to provide sensory innervation and motor control to each part of the compound muscle. As they converge, the anterior rami of adjacent spinal nerves blend their fibers,

producing a series of compound nerve trunks. Such a complex interwoven network of nerves is called a **nerve plexus** (PLEK-sus; *plexus*, braid).

Only the anterior rami form plexuses. These four major plexuses are the (1) *cervical plexus*, (2) *brachial plexus*, (3) *lumbar plexus*, and (4) *sacral plexus* (**Figure 13–9**). The nerves arising at these plexuses contain sensory as well as motor fibers because these nerves form from the fusion of anterior rami (**Spotlight Figure 13–8**).

Chapter 11 includes tables listing the nerves that control the major axial and appendicular muscles. As we proceed, it may be helpful to refer to Tables 11–2 through 11–19 in that chapter.

The Cervical Plexus

The **cervical plexus** consists of the anterior rami of spinal nerves C₁–C₅ (**Figures 13–9, 13–10**). The branches of the cervical

a Major nerves of the arm, forearm, and hand originating at the right brachial plexus, anterior view

Clinical Note Sensory Innervation in the Hand

Sensory function in the hand is serviced by three nerves of the brachial plexus. In carpal tunnel syndrome, compression of one or more nerves at the wrist causes changes or loss of sensation in the areas innervated by the affected nerve(s).

plexus innervate the muscles of the neck and extend into the thoracic cavity, where they control the diaphragm. The **phrenic** (FREN-ik) **nerve** is the major nerve of the cervical plexus. The left and right phrenic nerves supply the diaphragm, a key breathing muscle. Other branches of this nerve plexus are distributed to the skin of the neck and the superior part of the chest.

Tips

A useful mnemonic for remembering a function of three important cervical nerves is “C₃, C₄, C₅ keep the diaphragm alive.”

The Brachial Plexus

The **brachial plexus** innervates the pectoral girdle and upper limb, with contributions from the anterior rami (also called roots) of spinal nerves C₅–T₁ (**Figures 13–9, 13–11**). The brachial plexus can also have fibers from C₄, T₂, or both.

The rami of these spinal nerves form trunks and cords before they become peripheral nerves. **Trunks** are large bundles

of spinal nerve axons, which become the smaller branches called **cords**. We name both trunks and cords according to their location relative to the *axillary artery*, a large artery supplying the upper limb. Hence, we have *superior*, *middle*, and *inferior trunks*, and *lateral*, *medial*, and *posterior cords*. The lateral cord forms the **musculocutaneous nerve** exclusively and, together with the medial cord, contributes to the **median nerve**.

Figure 13–12 The Lumbar and Sacral Plexuses.

c Nerves of the lumbar and sacral plexuses, anterior view

Clinical Note Sensory Innervation in the Ankle and Foot

These illustrations show the normal distribution of sensory nerves innervating the ankle and foot. Mapping of touch and pain perception can be combined with observations of muscle function to detect nerve damage affecting specific peripheral nerves.

d Nerves of the sacral plexus, posterior view

The **ulnar nerve** is the other major nerve of the medial cord. The posterior cord gives rise to the **axillary nerve** and the **radial nerve**.

The Lumbar and Sacral Plexuses

The **lumbar plexus** and the **sacral plexus** arise from the lumbar and sacral segments of the spinal cord, respectively. The nerves arising at these plexuses innervate the pelvic girdle and lower limbs (**Figures 13-9, 13-12**).

The lumbar plexus contains axons from the anterior rami of spinal nerves T_{12} – L_4 . The major nerves of this plexus are the **genitofemoral nerve**, the **lateral femoral cutaneous nerve**, and the **femoral nerve**.

The sacral plexus contains axons from the anterior rami of spinal nerves L_4 – S_4 . Two major nerves arise at this plexus: the

sciatic (sĭ-AT-ik) **nerve** and the **pudendal nerve**. The sciatic nerve passes posterior to the femur, deep to the long head of the biceps femoris. As it approaches the knee, the sciatic nerve divides into two branches: the **common fibular nerve** (or *common peroneal nerve*) and the **tibial nerve**. The **sural nerve**, formed by branches of the tibial nerve, is a sensory nerve innervating the lateral portion of the foot. A section of this nerve is often removed for use in nerve grafts.

Discussions of motor performance usually make a distinction between the conscious ability to control motor function—something that requires communication and feedback between the brain and spinal cord—and automatic motor responses coordinated entirely within the spinal cord. These automatic responses, called reflexes, are motor responses to specific stimuli. In the rest of this chapter, we look at how

sensory neurons, interneurons, and motor neurons interconnect, and how these interconnections can produce both simple and complex reflexes.

✓ Checkpoint

9. Identify the major networks of nerves known as plexuses.
10. An anesthetic blocks the function of the posterior rami of the cervical spinal nerves. Which areas of the body will be affected?
11. Injury to which of the nerve plexuses would interfere with the ability to breathe?
12. Compression of which nerve produces the sensation that one's leg has "fallen asleep"?

See the blue Answers tab at the back of the book.

13-5 Interneurons are organized into functional groups called neuronal pools

13 Learning Outcome Discuss the significance of neuronal pools and describe the major patterns of interaction among neurons within and among these pools.

The body has about 10 million sensory neurons, 0.5 million motor neurons, and 20 *billion* interneurons. The sensory neurons deliver information to the CNS. The motor neurons distribute commands to peripheral effectors, such as skeletal muscles. Interactions among interneurons provide the interpretation, planning, and coordination of incoming and outgoing signals.

The billions of interneurons of the CNS are organized into a few hundred to a few thousand **neuronal pools**—functional groups of interconnected neurons. A neuronal pool may be scattered, involving neurons in several regions of the brain, or localized, with neurons restricted to one specific location in the brain or spinal cord.

Each pool has a limited number of input sources and output destinations. Each pool may contain both excitatory and inhibitory neurons. The output of the entire neuronal pool may stimulate or depress activity in other parts of the brain or spinal cord, affecting the interpretation of sensory information or the coordination of motor commands.

The pattern of interaction among neurons provides clues to the functional characteristics of a neuronal pool. We refer to the "wiring diagrams" in **Figure 13-13** as *neural circuits*, just as we refer to electrical circuits in the wiring of a house. We can distinguish five circuit patterns: *divergence*, *convergence*, *serial processing*, *parallel processing*, and *reverberation*.

- **Divergence** is the spread of information from one neuron to several neurons (**Figure 13-13a**), or from one pool to multiple pools. Divergence permits the broad distribution of a specific input. Considerable divergence occurs when sensory neurons bring information into the CNS, because the information is distributed to neuronal pools throughout the spinal cord and brain. Visual information arriving from the eyes, for example, reaches consciousness at the same time it is distributed to areas of the brain that control posture and balance at the subconscious level.

Figure 13-13 Neural Circuits: The Organization of Neuronal Pools.

- In **convergence**, several neurons synapse on a single postsynaptic neuron (**Figure 13–13b**). Several patterns of activity in the presynaptic neurons can therefore have the same effect on the postsynaptic neuron. Through convergence, the same motor neurons can be subject to both conscious and subconscious control. For example, diaphragm and rib cage movements are controlled by the brain at the subconscious level. But the same motor neurons can be consciously controlled, as when a diver takes a deep breath and holds it. Two neuronal pools are involved, both synapsing on the same motor neurons.
- In **serial processing**, information is relayed in a stepwise fashion, from one neuron to another or from one neuronal pool to the next (**Figure 13–13c**). This pattern occurs as sensory information is relayed from one part of the brain to another. For example, pain sensations on their way to consciousness make stops at two neuronal pools along the pain pathway.
- **Parallel processing** occurs when several neurons or neuronal pools process the same information simultaneously (**Figure 13–13d**). Divergence must take place before parallel processing can occur. As a result, many responses can occur simultaneously. For example, stepping on a sharp object stimulates sensory neurons that distribute the information to several neuronal pools. As a result of parallel processing, someone might withdraw their foot, shift their weight, move their arms, feel the pain, and shout “Ouch!” at about the same time.
- In **reverberation**, collateral branches of axons somewhere along the circuit extend back toward the source of an impulse and further stimulate the presynaptic neurons (**Figure 13–13e**). Reverberation is like a positive feedback loop involving neurons: Once a reverberating circuit has been activated, it will continue to function until synaptic fatigue or inhibitory stimuli break the cycle. Reverberation can take place within a single neuronal pool, or it may involve a series of interconnected pools. Highly complicated examples of reverberation among neuronal pools in the brain may help maintain consciousness, muscular coordination, and normal breathing.

The functions of the nervous system depend on the interactions among neurons organized in neuronal pools. The most complex neural processing steps take place between the spinal cord and brain. The simplest steps occur between the PNS and the spinal cord. These steps control reflexes that are a bit like Legos: Individually, the reflexes are quite simple, but they can be combined in a great variety of ways to create very complex responses. For this reason, reflexes are the basic building blocks of neural function, as described in the next section.

Checkpoint

13. Define neuronal pool.
14. List the five neuronal pool circuit patterns.

See the blue Answers tab at the back of the book.

13-6 The different types of neural reflexes are all rapid, automatic responses to stimuli

Learning Outcome Describe the steps in a neural reflex and classify the types of reflexes.

Conditions inside or outside the body can change quickly and unexpectedly. **Reflexes**, which are rapid and automatic responses to specific stimuli, preserve homeostasis by making quick adjustments in the function of organs or organ systems. The response shows little variability: Each time a particular reflex is activated, it normally produces the same motor response.

In Chapter 1, we introduced the basic functional components involved in all types of homeostatic regulation: a *receptor*, a *control center* (or *integration center*), and an *effector*. Here we consider *neural reflexes*, in which sensory fibers deliver information from peripheral receptors to an integration center in the CNS, and motor fibers carry motor commands to peripheral effectors. This includes the events that happen when a reflex is triggered, as well as the types of neural reflexes. In Chapter 18, we examine a *neuroendocrine response reflex*, in which hormones in the bloodstream carry the commands to peripheral tissues and organs.

The Reflex Arc

The route followed by nerve impulses to produce a reflex is called a **reflex arc**. **Spotlight Figure 13–14a** diagrams the five steps in a simple neural reflex.

1 Arrival of a Stimulus and Activation of a Receptor. Reflex arcs begin with activation of a **receptor**, which may be a specialized cell or the dendrites of a sensory neuron. Receptors are sensitive to physical or chemical changes in the body or to changes in the external environment. We introduced the general categories of sensory receptors in Chapter 12. If one leans on a tack, for example, pain receptors in the palm of the hand are activated. These receptors, the dendrites of sensory neurons, respond to stimuli that cause or accompany tissue damage. (We discuss the link between receptor stimulation and sensory neuron activation further in Chapter 15.)

2 Activation of a Sensory Neuron. When the dendrites are stretched, a graded depolarization results that leads to the formation and propagation of action potentials along the axons of the sensory neurons. This information reaches the spinal cord by way of a posterior root. In our example, **1** and **2** involve the same cell. However, the two steps may involve

Reflexes are rapid, automatic responses to specific stimuli. They preserve homeostasis by making rapid adjustments in the function of organs or organ systems.

a EVENTS IN A REFLEX ARC

The “wiring” of a single reflex is called a **reflex arc**. It begins at a receptor and ends at a peripheral effector such as a muscle fiber or a gland cell. A simple reflex arc, such as this withdrawal reflex, consists of five steps.

MONOSYNAPTIC REFLEXES

In the simplest reflex arc, a sensory neuron synapses directly on a motor neuron. Because there is only one synapse, it is called a **monosynaptic reflex**. Transmission across a chemical synapse always involves a synaptic delay, but with only one synapse, the delay between the stimulus and the response is minimized.

b Stretch Reflex

The **stretch reflex** is an example of a monosynaptic reflex. Because there is only one synapse, there is little delay between sensory input and motor output. These reflexes control the most rapid motor responses of the nervous system. A stretch reflex provides automatic regulation of skeletal muscle length.

The **patellar reflex** is an example of a stretch reflex. The stimulus is a tap on the patellar tendon that stretches receptors within the quadriceps femoris. The response is a brief contraction of those muscles, which produces a noticeable kick.

POLYSYNAPTIC REFLEXES

Polysynaptic reflexes can produce far more complicated responses than monosynaptic reflexes, because the interneurons can control motor neurons that activate several muscle groups simultaneously.

Withdrawal Reflex

A **withdrawal reflex** moves affected parts of the body away from a stimulus. A **flexor reflex** is an example of a withdrawal reflex that affects the muscles of a limb. In this example, the stimulus of a hot frying pan causes the contraction of the flexor muscles of the arm, yanking the forearm and hand away from the pan. This response occurs while pain sensations are simultaneously ascending to the brain.

Crossed Extensor Reflex

A **crossed extensor reflex** involves a contralateral reflex arc (*contra*, opposite). In other words, a motor response to the stimulus also occurs on a side opposite the stimulus. The crossed extensor reflex complements the flexor reflex, and the two occur simultaneously. When you step on a tack, the flexor reflex pulls the affected foot away from the ground, while the crossed extensor reflex straightens the other leg to support your body weight. In the crossed extensor reflex, interneurons responding to the pain have axons that cross to the other side of the spinal cord. There they stimulate motor neurons that control the extensor muscles of the uninjured leg. As a result, your opposite leg straightens to support the shifting weight. Reverberating circuits use positive feedback to ensure that the movement lasts long enough to be effective. All of this happens without motor commands from higher centers of the brain.

KEY

- - - Motor neuron (inhibited)
- Excitatory interneuron
- - - Inhibitory interneuron
- Motor neuron (stimulated)

different cells. For example, reflexes triggered by loud sounds begin when receptor cells in the internal ear release neurotransmitters that stimulate sensory neurons.

3 Information Processing in the CNS. In our example, information processing begins when excitatory neurotransmitter molecules, released by the axon terminal of a sensory neuron, arrive at the postsynaptic membrane of an interneuron. The neurotransmitter produces an excitatory postsynaptic potential (EPSP), which is integrated with other stimuli arriving at the postsynaptic cell at that moment. The information processing is thus performed by the interneuron. Different types of reflexes might involve varying numbers of interneurons (covered in Section 13-7).

4 Activation of a Motor Neuron. The axons of the stimulated motor neurons carry action potentials into the periphery—in this example, through the anterior root of a spinal nerve.

5 Response by a Peripheral Effector. The release of neurotransmitters by the motor neurons at axon terminals then leads to a response by a peripheral effector—in this case, skeletal muscle contraction pulls the hand away from the tack.

A reflex response generally removes or opposes the original stimulus, and this is an example of *negative feedback*. In the simplest reflexes, such as the *stretch reflex*, the sensory neuron innervates a motor neuron directly. However, reflexes may be integrated to produce complex movements that support or enhance the primary response. Two examples are given

in **Spotlight Figure 13-14**. By opposing potentially harmful changes in the internal or external environment, reflexes play an important role in homeostasis. However, the immediate reflex response is typically not the only response to a stimulus. Reflexes may be integrated to produce complex movements that support or enhance the primary response. The other responses, which are directed by the brain, involve multiple synapses and take longer to organize and coordinate.

Classification of Reflexes

There are several different methods of classifying reflexes. They can be classified based on (1) their development, (2) the nature of the resulting motor response, (3) the complexity of the neural circuit involved, and (4) the site of information processing. Keep in mind that these categories are not mutually exclusive; they represent different ways of describing a single reflex (**Figure 13-15**).

Development of Reflexes

Reflexes can be either *innate* (inborn) or *acquired* (learned). **Innate reflexes** result from the connections that form between neurons during development. Such reflexes generally appear in a predictable sequence, from the simplest reflex responses (withdrawal from pain) to more complex motor patterns (chewing, sucking, or tracking objects with the eyes). The neural connections responsible for the basic motor patterns of an

Figure 13-15 The Classification of Reflexes.

What are the four ways reflexes can be classified?

innate reflex are genetically programmed. Examples include the reflexive movement of the hand away from a hot stovetop and blinking when the eyelashes are touched.

More complex, learned motor patterns are called **acquired reflexes**. For example, an experienced driver steps on the brake when trouble appears ahead, or a professional skier makes equally quick adjustments in body position while racing. These motor responses are rapid and automatic, but they were learned rather than preestablished. Repetition enhances such reflexes.

The distinction between innate and acquired reflexes is not absolute. Some people can learn motor patterns more quickly than others. The differences probably have a genetic basis.

Most reflexes, whether innate or acquired, can be modified over time or suppressed through conscious effort. For example, a tightrope walker carefully making their way over the Grand Canyon would probably ignore a bee sting on their hand. Under other circumstances, they would probably withdraw their hand immediately, while shouting and thrashing about as well.

Nature of the Motor Response

Reflexes can be either *somatic* or *visceral*, depending on what type of motor responses they involve. **Somatic reflexes** provide a mechanism for the involuntary control of the muscular system. There are many types of somatic reflexes. For example, *superficial reflexes* are triggered by stimuli at the skin or mucous membranes. *Stretch reflexes* are triggered by the sudden elongation of a tendon, and thus of the muscle to which it attaches. A familiar example is the *patellar*, or *knee-jerk*, *reflex* that is usually tested during physical exams. These reflexes are also known as *deep tendon reflexes*. **Visceral reflexes**, or *autonomic reflexes*, control the activities of other systems. We consider somatic reflexes in detail in Section 13-7 and visceral reflexes in Chapter 16.

The movements directed by somatic reflexes are neither delicate nor precise. You might wonder why they exist at all, because we have voluntary control over the same muscles. In fact, somatic reflexes are vital, primarily because they are *immediate*. Making decisions and coordinating voluntary responses take time. In an emergency—as when a person slips while walking down a flight of stairs, or accidentally presses their hand against a knife edge—any delay increases the likelihood of severe injury. Thus, somatic reflexes provide a rapid response that can be modified later, if necessary, by voluntary motor commands.

Complexity of the Neural Circuit

Reflexes can also be defined as either *monosynaptic* or *polysynaptic* by how many neurons their circuits involve. **Monosynaptic reflexes** involve the simplest reflex arc. In these reflexes, the sensory neuron innervates a motor neuron directly. In that case, the motor neuron performs the information processing. Most reflexes are more complicated, however, and have at least one interneuron between the sensory neuron and the motor neuron. These types are called **polysynaptic reflexes**.

Polysynaptic reflexes have a longer delay between stimulus and response. The length of the delay is proportional to the number of synapses involved. Because this classification method for reflexes focuses on functional organization, this is the system that we use in the rest of the chapter. We discuss details and examples of these types of reflexes in the next section. **Spotlight Figure 13-14** highlights these reflexes.

Site of Information Processing

There is one final classification system for reflexes we should mention briefly, which is based on where they are processed. In **spinal reflexes**, the important interconnections and processing events occur in the spinal cord. We consider reflexes processed in the brain, called **cranial reflexes**, in Chapters 14, 16, and 17.

Checkpoint

15. Define reflex.
16. What is the minimum number of neurons in a reflex arc?
17. One of the first somatic reflexes to develop is the suck reflex. Which type of reflex is this?

See the blue Answers tab at the back of the book.

13-7 Monosynaptic reflexes produce simple responses, while polysynaptic reflexes can produce complex behaviors

Learning Outcome Distinguish among the types of motor responses produced by various reflexes and explain how reflexes interact to produce complex behaviors.

As we discussed, spinal reflexes range in complexity from simple monosynaptic reflexes involving a single segment of the spinal cord to polysynaptic reflexes that involve many segments. In the most complicated polysynaptic reflexes, called **intersegmental reflex arcs**, many segments interact to produce a coordinated, highly variable motor response. Next we consider both types of reflexes in greater detail.

Monosynaptic Reflexes

In monosynaptic reflexes, there is little delay between sensory input and motor output. These reflexes control the most rapid, *stereotyped* (preexisting, mechanically repetitive) *motor responses* of the nervous system to specific stimuli. A common example of how these reflexes work is described next.

The Stretch Reflex and Muscle Spindles

The best-known monosynaptic reflex is the **stretch reflex**, which automatically regulates skeletal muscle length. An example is the knee-jerk, or **patellar reflex**. When a physician taps a person's patellar tendon with a reflex hammer, receptors in the quadriceps femoris are stretched (**Spotlight Figure 13-14b**). The distortion of the receptors in turn stimulates sensory

neurons that extend into the spinal cord, where they synapse on motor neurons that control the motor units in the stretched muscle. This leads to a reflexive contraction of the stretched muscle that extends the knee in a brief kick.

To summarize: The stimulus (increasing muscle length) activates a sensory neuron, which triggers an immediate motor response (contraction of the stretched muscle) that counteracts the stimulus. The entire reflex is completed within 20–40 msec because the action potentials traveling toward and away from the spinal cord are propagated along large, myelinated Type A fibers.

Stretch reflexes are found all over the body, especially in places where automatic responses to maintain upright stance and posture are needed. Let's look in detail at the function of these reflexes, including the sensory receptors involved in the stretch reflex, which are called **muscle spindles**.

Muscle Spindle Structure. Each muscle spindle consists of a bundle of small, specialized skeletal muscle fibers called **intrafusal muscle fibers** (Figure 13–16). About the size and shape of a rice grain, a muscle spindle is surrounded by larger skeletal muscle fibers, called **extrafusal muscle fibers**. These fibers are responsible for the resting muscle tone and, at greater levels of stimulation, for the contraction of the entire muscle.

Both sensory and motor neurons innervate each intrafusal fiber. The dendrites of the sensory neuron spiral around the intrafusal fiber in a central sensory region. Axons from spinal motor neurons form neuromuscular junctions on either end of this fiber. Motor neurons innervating intrafusal fibers are called **gamma motor neurons**. Their axons are called **gamma efferents**.

Figure 13–16 A Muscle Spindle. The location, structure, and innervation of a muscle spindle.

An intrafusal fiber has one set of myofibrils at each end. These myofibrils run from the end of the intrafusal fiber only to the sarcolemma in the central region that is closely monitored by the sensory neuron.

Function of Muscle Spindles. The stretching of muscle spindles produces a sudden burst of activity in the sensory neurons that monitor them. This in turn leads to stimulation of motor neurons that control the motor units in the stretched muscle. The result is rapid muscle shortening, which returns the muscle spindles to their resting length. The rate of action potential generation in the sensory neurons then decreases, causing a drop in muscle tone to the resting level.

Now let's learn how the muscle spindle normally functions as a sensory receptor and look at its effects on the surrounding extrafusal fibers. The sensory neuron is always active, conducting impulses to the CNS. The axon enters the CNS in a posterior root and synapses on motor neurons in the anterior horn of the spinal cord. Axon collaterals distribute the information to the brain, providing information about the muscle spindle. Stretching the central portion of the intrafusal fiber distorts the dendrites and stimulates the sensory neuron, increasing the frequency of action potential generation. Compressing the central portion inhibits the sensory neuron, decreasing the frequency of action potential generation.

The axon of the sensory neuron synapses on CNS motor neurons that control the extrafusal muscle fibers of the same muscle. An increase in sensory neuron stimulation, caused by stretching of the intrafusal fiber, increases stimulation to the motor neuron controlling the surrounding extrafusal fibers, so muscle tone increases. This increase provides automatic resistance that reduces the chance of muscle damage due to overstretching. The patellar reflex and similar reflexes serve this function.

A decrease in the stimulation of the sensory neuron, due to compression of the intrafusal fiber, leads to a decrease in the stimulation of the motor neuron controlling the surrounding extrafusal fibers, so muscle tone decreases. This decrease reduces resistance to the movement under way. For example, if the elbow is flexed and gravity extends it, the triceps brachii muscle, which is compressed by this movement, relaxes.

Now let's turn to the role of the gamma efferents, which enable the CNS to adjust the sensitivity of the muscle spindle. Gamma efferents play a vital role whenever voluntary contractions change the length of a muscle. Impulses arriving over gamma efferents cause the contraction of myofibrils in the intrafusal fibers as the biceps brachii shortens. The myofibrils pull on the sarcolemma in the central portion of the intrafusal fiber—the region monitored by the sensory neuron—until that membrane is stretched to its normal resting length. As a result, the muscle spindles remain sensitive to any externally imposed changes in muscle length. For this reason, if someone drops a ball into the palm when the elbow is partially flexed, the muscle spindles automatically adjust the muscle tone to compensate for the increased load.

Postural Reflexes

Many of the body's reflexes, including both stretch reflexes and complex polysynaptic reflexes, are **postural reflexes**—reflexes that help a person maintain an upright posture. Standing, for example, involves a cooperative effort by many muscle groups. Some of these muscles work in opposition to one another, exerting forces that keep the body's weight balanced over the feet. If a person leans their body forward, stretch receptors in their calf muscles are stimulated. Those muscles then respond by contracting, returning their body to an upright position. If the muscles overcompensate and their body begins to lean back, their calf muscles relax. But then stretch receptors in muscles of their shins and thighs are stimulated, and the problem is corrected immediately.

Postural muscles generally maintain a firm muscle tone and have extremely sensitive stretch receptors. As a result, very fine adjustments are continually being made, and a person is not aware of the contraction and relaxation cycles.

Polysynaptic Reflexes

Polysynaptic reflexes can produce far more complicated responses than can monosynaptic reflexes. One reason is that the interneurons involved can control several muscle groups. Moreover, some of these interneurons release excitatory neurotransmitters (*excitatory interneurons*), and others release inhibitory neurotransmitters (*inhibitory interneurons*). This allows these interneurons to produce either excitatory or inhibitory postsynaptic potentials (EPSPs or IPSPs) at CNS motor nuclei. As a result, the response can involve the stimulation of some muscles and the inhibition of others.

Let's explore some of the different examples of polysynaptic reflexes.

The Tendon Reflex

The **tendon reflex** monitors the external tension produced during a muscular contraction and prevents tearing of the tendons. The sensory receptors for this reflex are *Golgi tendon organs*. They are stimulated when the collagen fibers are stretched to a dangerous degree. These receptors activate sensory neurons that stimulate inhibitory interneurons in the spinal cord. These interneurons in turn innervate the motor neurons controlling the skeletal muscle. The greater the tension in the tendon, the greater the inhibitory effect on the motor neurons. As a result, a skeletal muscle generally cannot develop enough tension to tear its tendons.

Withdrawal Reflexes

Withdrawal reflexes move affected parts of the body away from a stimulus. Painful stimuli trigger the strongest withdrawal reflexes, but these reflexes are also sometimes initiated by the stimulation of touch receptors or pressure receptors.

The **flexor reflex**, a representative withdrawal reflex, affects the muscles of a limb (**Spotlight Figure 13–14c**). Recall from Chapters 9 and 11 that flexion reduces the angle between two articulating bones and that the contractions of flexor muscles

perform this movement. If a cook grabs an unexpectedly hot pan on a stove, a dramatic flexor reflex will occur. When the pain receptors in their hand are stimulated, the sensory neurons activate interneurons in the spinal cord that stimulate motor neurons in the anterior horns. The result is a contraction of flexor muscles that yanks the cook's hand away from the stove.

When a specific muscle contracts, opposing muscles must relax to permit the movement. For example, flexor muscles that bend the elbow (such as the biceps brachii) are opposed by extensor muscles (such as the triceps brachii) that straighten it out. A potential conflict exists: In theory, the contraction of a flexor muscle should trigger a stretch reflex in the extensors that would cause them to contract, opposing the movement. Interneurons in the spinal cord prevent such competition through **reciprocal inhibition**. When one set of motor neurons is stimulated, those neurons that control antagonistic muscles are inhibited. The term *reciprocal* refers to the fact that the system works both ways. When the flexors contract, the extensors relax, and when the extensors contract, the flexors relax.

Withdrawal reflexes are much more complex than any monosynaptic reflex. They also show tremendous versatility because the sensory neurons activate many pools of interneurons. If the stimuli are strong, interneurons will carry excitatory and inhibitory impulses up and down the spinal cord, affecting motor neurons in many segments. The result is always the same: a coordinated movement away from the stimulus. But the distribution of the effects and the strength and character of the motor responses depend on the intensity and location of the stimulus.

Mild discomfort might provoke a brief contraction in muscles of the hand and wrist. More powerful stimuli would produce coordinated muscular contractions affecting the positions of the hand, wrist, forearm, and arm. Severe pain would also stimulate contractions of the arm, shoulder, and trunk muscles. These contractions could last for several seconds, due to the activation of reverberating circuits. In contrast, monosynaptic reflexes are invariable and brief.

Crossed Extensor Reflexes

The stretch, tendon, and withdrawal reflexes involve *ipsilateral* (*ipsi*, same + *lateral*, side) *reflex arcs*: The sensory stimulus and the motor response occur on the same side of the body. The crossed extensor reflex involves a *contralateral reflex arc* (*contra*, opposite), because the motor response occurs on the side opposite the stimulus. Please read the information on this type of reflex in **Spotlight Figure 13–14d** before moving on.

General Characteristics of Polysynaptic Reflexes

Polysynaptic reflexes range in complexity from a simple tendon reflex to the complex and variable reflexes associated with standing, walking, and running. Yet all polysynaptic reflexes share the following basic characteristics:

- *They Involve Pools of Interneurons.* Processing takes place in pools of interneurons before motor neurons are activated.

The result may be excitation or inhibition. The tendon reflex inhibits motor neurons, and the flexor and crossed extensor reflexes direct specific muscle contractions.

- *They Involve More Than One Spinal Segment.* The interneuron pools extend across spinal segments and may activate muscle groups in many parts of the body.
- *They Involve Reciprocal Inhibition.* Reciprocal inhibition coordinates muscular contractions and reduces resistance to movement. In the flexor and crossed extensor reflexes, the contraction of one muscle group is associated with the inhibition of opposing muscles.
- *They Have Reverberating Circuits That Prolong the Reflexive Motor Response.* Positive feedback between interneurons that innervate motor neurons and the processing pool maintains the stimulation even after the initial stimulus has faded.
- *Several Reflexes May Cooperate to Produce a Coordinated, Controlled Response.* As a reflex movement gets under way, antagonistic reflexes are inhibited. For example, during the stretch reflex, antagonistic muscles are inhibited. In contrast, in the tendon reflex, antagonistic muscles are stimulated. In complex polysynaptic reflexes, commands may be distributed along the length of the spinal cord, producing a well-coordinated response.

✓ Checkpoint

18. Identify the basic characteristics of polysynaptic reflexes.
19. For the patellar (knee-jerk) reflex, how would the stimulation of the muscle spindle by gamma motor neurons affect the speed of the reflex?
20. A weightlifter is straining to lift a 200-kg barbell above his head. Shortly after he lifts it to chest height, his muscles appear to relax and he drops the barbell. Which reflex has occurred?
21. During a withdrawal reflex of the foot, what happens to the limb on the side opposite the stimulus? What is this response called?

See the blue Answers tab at the back of the book.

13-8 The brain can affect spinal cord-based reflexes

Learning Outcome Explain how higher brain centers control and modify reflex responses.

Reflex motor behaviors happen automatically, without instructions from higher brain centers. However, higher centers can have a profound effect on the performance of a reflex. Processing centers in the brain can facilitate or inhibit reflex motor patterns based in the spinal cord. Descending tracts originating in the brain synapse on interneurons and motor neurons throughout the spinal cord. These synapses are

continuously active, producing EPSPs or IPSPs at the postsynaptic membrane. Let's find out how this process works.

Voluntary Movements and Reflex Motor Patterns

Spinal reflexes produce consistent, stereotyped motor patterns that are triggered by specific external stimuli. However, the same motor patterns can also be activated as needed by centers in the brain. By making use of these pre-existing patterns, relatively few descending fibers can control complex motor functions.

For example, neuronal pools in the spinal cord direct the motor patterns for walking, running, and jumping. The descending pathways from the brain provide appropriate facilitation, inhibition, or "fine-tuning" of the established patterns. This is a very efficient system that is similar to an order given in a military drill: A single command triggers a complex, predetermined sequence of events.

Motor control involves a series of interacting levels. At the lowest level are monosynaptic reflexes that are rapid but stereotyped and relatively inflexible. At the highest level, centers in the brain can modulate or build on reflexive motor patterns.

Reinforcement and Inhibition

A single EPSP may not depolarize the postsynaptic neuron sufficiently to generate an action potential, but it does make that neuron more sensitive to other excitatory stimuli. We introduced this process of *facilitation* in Chapter 12. Alternatively, an IPSP makes the neuron less responsive to excitatory stimulation through the process of *inhibition*. By stimulating excitatory or inhibitory interneurons within the brainstem or spinal cord, higher centers can adjust the sensitivity of reflexes by creating EPSPs or IPSPs at the motor neurons involved in reflex responses.

When many of the excitatory synapses are chronically active, the postsynaptic neuron can enter a state of generalized facilitation. This facilitation of reflexes can result in **reinforcement**, an enhancement of spinal reflexes. Reinforcement techniques are useful in clinical situations. For example, a stimulus may fail to elicit a particular reflex response during a clinical exam. There can be many reasons for the failure. The person may be consciously suppressing the response, the nerves involved may be damaged, or there may be underlying problems inside the CNS.

The clinician may then attempt the reflex procedure again, this time using reinforcement. For example, a method used to overemphasize the patellar reflex is called the Jendrassik maneuver. To do this, the subject hooks the hands together by interlocking the fingers and then tries to pull the hands apart while a light tap is applied to the patellar tendon. This reinforcement produces a big kick rather than a twitch.

Reinforced reflexes are usually too strong to suppress consciously. If the reflex still fails to appear, the likelihood of nerve or CNS damage is increased. The clinician may then order

more sophisticated tests, such as nerve conduction studies or scans.

Other descending fibers have an inhibitory effect on spinal reflexes. In adults, stroking the lateral sole of the foot produces a curling of the toes, called a **plantar reflex**, after about a 1-second delay (**Figure 13-17a**). In contrast, stroking an infant's foot on the lateral sole produces a fanning of the toes known as the **Babinski reflex** (**Figure 13-17b**). This response disappears around age 2 as descending motor pathways develop. If either the higher centers or the descending tracts are damaged, the Babinski sign reappears in an adult. As a result, clinicians often test this reflex when CNS injury is suspected.

Figure 13-17 The Plantar Reflex and Babinski Reflex.

Tips

Facilitation and inhibition are similar to what happens when a symphony conductor raises or lowers one hand to control the music's volume while keeping the rhythm going with the baton hand: The basic pattern of beats doesn't change, but the loudness does.

Checkpoint

22. Define reinforcement as it pertains to spinal reflexes.
23. After injuring her back, Tina exhibits a Babinski reflex. What does this imply about Tina's injury?

See the blue Answers tab at the back of the book.

13 Chapter Review

Study Outline

An Introduction to the Spinal Cord, Spinal Nerves, and Spinal Reflexes

1. The nervous system has input pathways that route sensations, and processing centers that prioritize and distribute information.

13-1 This text's coverage of the nervous system parallels its simple-to-complex levels of organization

2. The CNS consists of the brain and spinal cord; the PNS includes cranial nerves and spinal nerves. (*Figure 13-1*)

13-2 The spinal cord is surrounded by three meninges and has spinal nerve roots

3. The adult spinal cord includes two localized **enlargements**, which provide innervation to the limbs. The spinal cord has 31 segments, each associated with a pair of **posterior roots** or **dorsal roots** and a pair of **anterior roots** or **ventral roots**. (*Figure 13-2*)
4. The **filum terminale** (a strand of fibrous tissue) originates at the **conus medullaris** and ultimately becomes part of the **coccygeal ligament**. (*Figure 13-2*)
5. **Spinal nerves** are **mixed nerves**: They contain both afferent (sensory) and efferent (motor) fibers.

6. The three **spinal meninges** provide physical stability and shock absorption for nervous tissues of the spinal cord; the **cranial meninges** surround the brain. (*Figure 13-3*)
7. The **dura mater**, the outer meningeal layer, covers the spinal cord; inferiorly, it tapers into the **coccygeal ligament**. The **epidural space** separates the dura mater from the walls of the vertebral canal. (*Figures 13-3, 13-4*)
8. Interior to the inner surface of the dura mater are the **subdural space**, the **arachnoid mater** (the second meningeal layer), and the **subarachnoid space**. The subarachnoid space contains **cerebrospinal fluid (CSF)**, which acts as a shock absorber and a diffusion medium for dissolved gases, nutrients, chemical messengers, and waste products. (*Figures 13-3, 13-4*)

9. The **pia mater**, a meshwork of elastic and collagen fibers, is the innermost meningeal layer. **Denticulate ligaments** extend from the pia mater to the dura mater. (Figures 13–3, 13–4)

13-3 Spinal cord gray matter integrates information and initiates commands, and white matter carries information from place to place

10. The white matter of the spinal cord contains myelinated and unmyelinated axons, and the gray matter contains cell bodies of neurons and neuroglia and unmyelinated axons. The projections of gray matter toward the outer surface of the spinal cord are called **horns**. (Figure 13–5)
11. The **posterior horns** contain somatic and visceral sensory nuclei; nuclei in the **anterior horns** function in somatic motor control. The **lateral horns** contain visceral motor neurons. The **gray commissures** contain axons that cross from one side of the spinal cord to the other. (Figure 13–5)
12. The white matter can be divided into six **columns**, each of which contains **tracts**. **Ascending tracts** relay information from the spinal cord to the brain, and **descending tracts** carry information from the brain to the spinal cord. (Figure 13–5)

13-4 Spinal nerves extend to form peripheral nerves, sometimes forming plexuses along the way; these nerves carry sensory and motor information

13. There are 31 pairs of spinal nerves. Each has an **epineurium** (outermost layer), a **perineurium**, and an **endoneurium** (innermost layer). (Figure 13–6)
14. Each pair of spinal nerves monitors a region of the body surface called a **dermatome**. (Figure 13–7)
15. A typical spinal nerve has a **white ramus communicans** (containing myelinated axons), a **gray ramus communicans** (containing unmyelinated fibers that innervate glands and smooth muscles in the body wall or limbs), a **posterior ramus** (providing sensory and motor innervation to the skin and muscles of the back), and an **anterior ramus** (supplying the ventrolateral body surface, structures in the body wall, and the limbs). (Spotlight Figure 13–8)
16. A complex, interwoven network of nerves is a **nerve plexus**. The four large plexuses are the **cervical plexus**, the **brachial plexus**, the **lumbar plexus**, and the **sacral plexus**. (Figures 13–9 to 13–12)

13-5 Interneurons are organized into functional groups called neuronal pools

17. The body has sensory neurons, which deliver information to the CNS; motor neurons, which distribute commands to peripheral effectors; and interneurons, which interpret information and coordinate responses.
18. An organized, functional group of interconnected interneurons is a **neuronal pool**.
19. The neural circuit patterns are **divergence**, **convergence**, **serial processing**, **parallel processing**, and **reverberation**. (Figure 13–13)

13-6 The different types of neural reflexes are all rapid, automatic responses to stimuli

20. A **neural reflex** involves sensory fibers delivering information to the CNS, and motor fibers carrying commands to the effectors by the PNS.
21. A **reflex arc** is the neural “wiring” of a single reflex. (Spotlight Figure 13–14)

22. The five steps involved in a neural reflex are (1) the arrival of a stimulus and activation of a receptor, (2) the activation of a sensory neuron, (3) information processing in the CNS, (4) the activation of a motor neuron, and (5) a response by an effector. (Spotlight Figure 13–14)
23. Reflexes are classified according to (1) their development (innate or acquired), (2) the nature of the resulting motor response, (3) the complexity of the neural circuit involved, and (4) the site of information processing. (Figure 13–15)
24. **Innate reflexes** result from the genetically determined connections that form between neurons during development. **Acquired reflexes** are learned and typically are more complex.
25. **Somatic reflexes** control skeletal muscles; **visceral reflexes** (*autonomic reflexes*) control the activities of other systems.
26. In a **monosynaptic reflex**—the simplest reflex arc—a sensory neuron synapses directly on a motor neuron, which acts as the processing center. A **polysynaptic reflex** has at least one interneuron between the sensory afferent and the motor efferent, and there is a longer delay between stimulus and response. (Spotlight Figure 13–14)
27. Reflexes processed in the brain are **cranial reflexes**. In a **spinal reflex**, the important interconnections and processing events occur in the spinal cord.

13-7 Monosynaptic reflexes produce simple responses, while polysynaptic reflexes can produce complex behaviors

28. Spinal reflexes range from simple monosynaptic reflexes to more complex polysynaptic and **intersegmental reflexes**, in which many spinal segments interact to produce a coordinated motor response.
29. The **stretch reflex** (such as the **patellar**, or **knee-jerk, reflex**) is a monosynaptic reflex that automatically regulates skeletal muscle length and muscle tone. The sensory receptors involved are **muscle spindles**. (Spotlight Figure 13–14, Figure 13–16)
30. A **postural reflex** maintains a person’s upright posture.
31. Polysynaptic reflexes can produce more complicated responses than can monosynaptic reflexes. Examples include the **tendon reflex** (which monitors the tension produced during muscular contractions and prevents damage to tendons) and **withdrawal reflexes** (which move affected portions of the body away from a source of stimulation). The **flexor reflex** is a withdrawal reflex affecting the muscles of a limb. The **crossed extensor reflex** complements withdrawal reflexes. (Spotlight Figure 13–14)
32. All polysynaptic reflexes (1) involve pools of interneurons, (2) are intersegmental in distribution, (3) involve reciprocal inhibition, (4) have reverberating circuits, which prolong the reflexive motor response, and (5) can cooperate to produce a coordinated response.

13-8 The brain can affect spinal cord–based reflexes

33. The brain can facilitate or inhibit reflex motor patterns based in the spinal cord.
34. Motor control involves a series of interacting levels. Monosynaptic reflexes form the lowest level; at the highest level are the centers in the brain that can modulate or build on reflexive motor patterns.
35. Facilitation can produce an enhancement of spinal reflexes known as **reinforcement**. Spinal reflexes may also be inhibited, as when the **plantar reflex** in adults replaces the **Babinski reflex** in infants. (Figure 13–17)

Review Questions

See the blue Answers tab at the back of the book.

LEVEL 1 Reviewing Facts and Terms

1. Label the anatomical structures of the spinal cord in the following figure.

- | | |
|-----------|-----------|
| (a) _____ | (b) _____ |
| (c) _____ | (d) _____ |
| (e) _____ | (f) _____ |
| (g) _____ | (h) _____ |
| (i) _____ | |

2. The posterior roots of each spinal segment **(a)** contain the axons of motor neurons, **(b)** bring sensory information into the spinal cord, **(c)** connect to rami communicantes, **(d)** contain the axons that control visceral effectors.
3. A spinal nerve **(a)** branches into a myelinated gray ramus communicans, **(b)** branches into a myelinated white ramus communicans, **(c)** remains confined within the vertebral column, **(d)** contains multiple spinal ganglia.
4. The cauda equina does *not* contain the **(a)** filum terminale, **(b)** conus medullaris, **(c)** anterior roots of spinal segments L2 to L5, **(d)** posterior roots of spinal segments L2 to S5, **(e)** anterior roots of spinal sacral segments.
5. Which of the following statements concerning the white matter of the spinal cord is *false*? **(a)** It contains both myelinated and unmyelinated axons. **(b)** It contains only myelinated axons. **(c)** It is divided into columns. **(d)** The columns contain bundles of axons called tracts. **(e)** There are descending and ascending tracts.
6. The following are the steps involved in a neural reflex.
 - (1) activation of a sensory neuron
 - (2) activation of a motor neuron
 - (3) response by an effector
 - (4) arrival of a stimulus and activation of a receptor
 - (5) information processing
 The proper sequence of these steps is
(a) 1, 3, 4, 5, 2. **(b)** 4, 5, 3, 1, 2.
(c) 4, 1, 5, 2, 3. **(d)** 4, 3, 1, 5, 2.
(e) 3, 1, 4, 5, 2.
7. The innermost connective tissue layer surrounding each of the spinal nerves is the **(a)** epineurium, **(b)** perineurium, **(c)** myelin sheath, **(d)** endoneurium.
8. The nerve that arises at the lumbar plexus and innervates the sartorius muscle is the **(a)** iliohypogastric nerve, **(b)** femoral nerve, **(c)** sciatic nerve, **(d)** obturator nerve.
9. The ulnar, radial, and median nerves are major nerves of the **(a)** cervical plexus, **(b)** brachial plexus, **(c)** lumbar plexus, **(d)** sacral plexus.
10. The synapsing of several neurons on the same postsynaptic neuron is called **(a)** serial processing, **(b)** reverberation, **(c)** divergence, **(d)** convergence.
11. The reflexes that control the most rapid, stereotyped motor responses to stimuli are **(a)** monosynaptic reflexes, **(b)** polysynaptic reflexes, **(c)** tendon reflexes, **(d)** extensor reflexes.
12. An example of a stretch reflex triggered by passive muscle movement is the **(a)** tendon reflex, **(b)** patellar reflex, **(c)** flexor reflex, **(d)** ipsilateral reflex.
13. The contraction of flexor muscles and the relaxation of extensor muscles illustrate the principle of **(a)** reverberating circuitry, **(b)** generalized facilitation, **(c)** reciprocal inhibition, **(d)** reinforcement.
14. Somatic reflexes control **(a)** skeletal muscles, **(b)** smooth muscles, **(c)** cardiac muscles, **(d)** glands.
15. Proceeding deep from the most superficial structure, number the following in the correct sequence.

(a) _____ walls of vertebral canal	(b) _____ dura mater
(c) _____ subdural space	(d) _____ epidural space
(e) _____ pia mater	(f) _____ arachnoid membrane
(g) _____ subarachnoid space	(h) _____ spinal cord

LEVEL 2 Reviewing Concepts

16. Explain the anatomical significance of the fact that spinal cord growth stops at age 4.
17. List, in sequence, the five steps involved in a neural reflex.
18. The innervation of the hand is provided by several nerves. Which nerve(s) innervates the anterior part of the little finger? **(a)** palmar digital nerves, **(b)** ulnar nerve, **(c)** radial nerve, **(d)** lateral antebrachial cutaneous nerve.
19. What is spinal anesthesia and what does it do?
20. If the posterior roots of the spinal nerves were damaged, what type of function would be affected?
21. In which meningeal space is cerebrospinal fluid (CSF) found? What are the functions of CSF?
22. What five characteristics are common to all polysynaptic reflexes?
23. Predict the effects on the body of a spinal cord transection at segment C₇. How would these effects differ from those of a spinal cord transection at segment T₁₀?
24. In adults, a safe location to perform a spinal tap is the **(a)** cervical region, **(b)** lower lumbar region, **(c)** upper thoracic region, **(d)** lower thoracic region, **(e)** brain.
25. Side-to-side movements of the spinal cord are prevented by the **(a)** filum terminale, **(b)** denticulate ligaments, **(c)** dura mater, **(d)** pia mater, **(e)** arachnoid mater.
26. Descending tracts **(a)** carry sensory information to the brain, **(b)** carry motor information to the brain, **(c)** carry sensory information from the brain, **(d)** carry motor commands to the spinal cord, **(e)** connect perceptive areas with the brain.
27. Why might a clinician try to ascertain nerve or CNS damage through the reinforcement of spinal reflexes?

LEVEL 3 Critical Thinking and Clinical Applications

28. Jules complains that when she wakes up in the morning, her thumb and forefinger are always "asleep." She mentions this condition to her physician, who asks Jules whether she sleeps with her wrists flexed. She replies that she does. The physician tells Jules that sleeping in that

position may compress a portion of one of her peripheral nerves, producing her symptoms. Which nerve is involved?

29. Dolores is close to giving birth to her second child. The birth of her first child took a long time and Dolores remembers the pain she suffered. She asks her doctor if something can be done to control the pain better this time. What does the gynecologist propose?
30. Bowel and urinary bladder control involve spinal reflex arcs that are located in the sacral region of the spinal cord. In both instances, two sphincter muscles—an inner sphincter of smooth muscle and an outer

sphincter of skeletal muscle—control the passage of wastes (feces and urine) out of the body. How would a transection of the spinal cord at the L_1 segment level affect an individual's bowel and bladder control?

31. After recovering from chickenpox, Jane is now suffering from a rash that appears as red spots arranged in a girdle-like pattern. The condition is rather painful, but her doctor assures her that treatment is available for this and that she can get cured even without treatment. What is Jane's condition and how has she developed this?

CLINICAL CASE Wrap-Up Prom Night

The emergency room team “log rolls” Grady over onto his side while maintaining his spinal alignment. The abrasions and bruising of his back are obvious. The doctor can feel that Grady's spinous processes, from the 7th cervical to the 11th thoracic vertebrae, are in good alignment. There is an obvious gap, however, between the 11th and 12th thoracic spinous processes. The 12th thoracic spinous process and lumbar spine are displaced lateral to the midline. Palpating in this area causes Grady a great deal of discomfort. Grady has no sensation inferior to his 11th thoracic dermatome, just inferior to the level of the navel. Grady also has no voluntary muscle control of any muscles of his hips or inferior limbs.

X-rays taken in the trauma room show a fracture dislocation of the thoracic spine between the 11th thoracic vertebra (T_{11}) and the

12th thoracic vertebra (T_{12}). An MRI confirms the clinical impression that Grady's spinal cord is completely disrupted at this level.

Grady's spine is surgically realigned and stabilized (fixed in place) with internal fixation (surgical wires and pins). This enables him to begin sitting within the first week after his accident. Within 2 weeks he is transferred to a spinal rehabilitation facility to begin working on independence as a person with paraplegia, who has lost motor control and sensation to the lower limbs (but not the upper limbs).

1. Will Grady regain motor or sensory activity in his lower extremities? Why or why not?
2. Would Grady exhibit plantar reflexes or Babinski reflexes? Why?

See the blue Answers tab at the back of the book.

Related Clinical Terms

areflexia: Absence of reflexes.

Brown-Sequard syndrome: Loss of sensation and motor function that results from unilateral spinal cord lesions. Proprioception loss and weakness occur ipsilateral to the lesion while pain and temperature loss occur contralateral.

equinovarus: The foot is plantar flexed, inverted, and adducted; also called *talipes equinovaglus*.

Erb palsy (Erb-Duchenne palsy): Obstetric condition characterized by paralysis or weakness of a newborn's upper arm muscles caused by a stretch injury to the brachial plexus.

hemiparesis: Slight paralysis or weakness affecting one side of the body.

Kernig sign: Symptom of meningitis where patient cannot extend the leg at the knee due to stiffness in the hamstring muscles.

myelography: A diagnostic procedure in which a radiopaque dye is introduced into the cerebrospinal fluid to obtain an x-ray image of the spinal cord and cauda equina.

nerve conduction study: Test often performed along with electromyography (EMG); the test stimulates certain nerves and records their ability to send an impulse to the muscle; it can indicate where any blockage of the nerve pathway exists.

nerve growth factor: A peptide that promotes the growth and maintenance of neurons. Other factors that are important to neuron growth and repair include BDNF, NT-3, NT-4, and GAP-43.

paraplegia: Paralysis involving a loss of motor control of the lower, but not the upper, limbs.

quadriplegia: Paralysis involving the loss of sensation and motor control of the upper and lower limbs.

spinal shock: Term applied to all phenomena surrounding physiological or anatomical transection of the spinal cord that results in temporary loss or depression of all or most spinal reflex activity inferior to the level of the injury.

tabes dorsalis: Slow progressive degeneration of the myelin layer of the sensory neurons of the spinal cord that occurs in the tertiary (third) phase of syphilis. Common signs and symptoms are pain, weakness, diminished reflexes, unsteady gait, and loss of coordination.

The Brain and Cranial Nerves

Learning Outcomes

These Learning Outcomes correspond by number to this chapter's sections and indicate what you should be able to do after completing the chapter.

- 14-1 ■ Name the major brain regions, vesicles, and ventricles, and describe the locations and functions of each.
- 14-2 ■ Explain how the brain is protected and supported, and discuss the formation, circulation, and function of cerebrospinal fluid.
- 14-3 ■ Describe the anatomical differences between the medulla oblongata and the spinal cord and identify the main components and functions of the medulla oblongata.
- 14-4 ■ List the main components of the pons and specify the functions of each.
- 14-5 ■ List the main components of the midbrain and specify the functions of each.
- 14-6 ■ List the main components of the cerebellum and specify the functions of each.
- 14-7 ■ List the main components of the diencephalon and specify the functions of each.
- 14-8 ■ Identify the main components of the limbic system and specify the locations and functions of each.
- 14-9 ■ Identify the major anatomical subdivisions and functions of the cerebrum and discuss the origin and significance of the major types of brain waves seen in an electroencephalogram (EEG).
- 14-10 ■ Describe representative examples of cranial reflexes that produce somatic responses or visceral responses to specific stimuli.

CLINICAL CASE The Bells!

Shane, a 63-year-old former builder from Perth, Australia, was enjoying his retirement. He exercised daily and went for regular medical check-ups and, apart from a dry cough a few weeks previously, he had been in good health for many years. However, one morning that all changed when he woke up and felt that something was very wrong with the left side of his face. He got out of bed and looked in the mirror and was shocked at what he saw: The left side of his face and mouth were drooping and only the right side of his face appeared to be able to smile. He also had difficulty closing his left eye. He called his wife, who was equally shocked when she saw the state he was in.

“Oh goodness, Shane! I think you might have had a stroke! I’ll call an ambulance.”

At the hospital, a neurologist examined Shane. “That’s interesting,” she said. “All of your signs and symptoms suggest that your condition is caused by a problem with just one nerve.” The doctor then ordered an MRI scan of Shane’s brain and some blood tests to try and get to the bottom of the case.

Which nerve is involved here? Has Shane had a stroke or is something else causing his problems? To find out, turn to the Clinical Case Wrap-Up at the end of the chapter.

14

An Introduction to the Brain and Cranial Nerves

In this chapter we introduce the functional organization of the *brain* and *cranial nerves* and describe simple *cranial reflexes*. The adult human brain contains almost 97% of the body’s nervous tissue. As we discussed in Chapter 12, the **brain** is responsible for integrating and processing sensory and motor information, as well as being the seat of higher mental functions such as intelligence, memory, and emotions.

A “typical” brain has a volume of 1200 mL (71 in.³). However, brain size varies considerably among individuals. The brains of males are, on average, about 10% larger than those of females, due to differences in average body size. No correlation exists between brain size and intelligence. Individuals with the smallest brains (750 mL) and the largest brains (2100 mL) are functionally normal.

14-1 The brain develops four major regions: the cerebrum, cerebellum, diencephalon, and brainstem

Learning Outcome Name the major brain regions, vesicles, and ventricles, and describe the locations and functions of each.

In this section we introduce the anatomical organization of the brain. We begin with an overview of the brain’s major regions and landmarks. Then we discuss the brain’s embryonic origins and some prominent internal cavities: the *ventricles* of the brain.

Major Brain Regions and Landmarks

There are four major brain regions: the *cerebrum*, *cerebellum*, *diencephalon*, and *brainstem*. **Figure 14-1** shows the boundaries and general functions of these regions.

The Cerebrum

The largest portion of the adult brain is the **cerebrum** (se-RE-brum; **Figure 14-1a**). Conscious thoughts, sensations, intellect, memory, and complex movements all originate in the cerebrum. It is made up of large, paired left and right **cerebral hemispheres**. The surfaces of the cerebral hemispheres are highly folded and covered by a collection of neurons that form a thin superficial layer of gray matter called the **cerebral cortex** (*cortex*, bark). This cerebral cortex forms a series of rounded elevations called **gyri** (JĪ-rĪ; singular, *gyrus*) that increase its surface area. The gyri are separated by shallow grooves called **sulci** (SUL-sĪ; singular, *sulcus*) or by deeper grooves called **fissures**. Fissures separate larger brain regions.

The Cerebellum

The **cerebellum** (ser-e-BEL-um) is the second-largest part of the brain (**Figure 14-1b**). It is partially hidden by the cerebral hemispheres. Like the cerebrum, the cerebellum has hemispheres covered by a sheet of gray matter called the *cerebellar cortex*. The cerebellum adjusts ongoing movements by comparing arriving sensations with previously experienced sensations, allowing a person to do the same movements over and over.

The Diencephalon

The other major anatomical regions of the brain can best be examined after the cerebral and cerebellar hemispheres have been removed. The walls of the **diencephalon** (dĪ-en-SEF-a-lon; *dia*, through + *encephalos*, brain) are composed of the *thalamus* (THAL-a-mus) and *hypothalamus* (**Figure 14-1c**). The thalamus contains relay and processing centers for sensory information. The *hypothalamus* (*hypo*-, below) is the floor of the diencephalon.

Figure 14–1 An Introduction to Brain Structures and Functions.

What structures make up the brainstem?

It contains centers involved with emotions, autonomic function, and hormone production. The *infundibulum*, a narrow stalk, connects the hypothalamus to the **pituitary gland**, a part of the endocrine system. This connection integrates the nervous and endocrine systems.

The Brainstem

The diencephalon is a structural and functional link between the cerebral hemispheres and the brainstem. The **brainstem** contains

a variety of important processing centers and nuclei (clearly distinguishable masses of brain neurons) that relay information headed to or from the cerebrum or cerebellum. The brainstem includes the *midbrain*, *pons*, and *medulla oblongata* (**Figure 14–1d,e,f**).

- The **midbrain** contains nuclei that process visual and auditory information and control reflexes triggered by these stimuli. For example, immediate, reflexive responses to a loud, unexpected noise (eye movements and head turning) are directed by nuclei in the midbrain. This region also

contains centers (groups of nerve cells governing a specific function) that help maintain consciousness (Figure 14-1d).

- The **pons** of the brain connects the cerebellum to the brainstem (*pons* is Latin for “bridge”). In addition to **tracts** (collections of CNS axons) and relay centers, the pons contains nuclei involved with somatic and visceral motor control (Figure 14-1e).
- The **medulla oblongata** connects the brain to the spinal cord. Near the pons, the posterior wall of the medulla oblongata is thin and membranous. The inferior portion of the medulla oblongata resembles the spinal cord in that it has a narrow **central canal**. The medulla oblongata relays sensory information to the thalamus and to centers in other portions of the brainstem. The medulla oblongata also contains major centers that regulate autonomic function, such as heart rate, blood pressure, and digestion (Figure 14-1f).

In considering the regions of the brain in this chapter, we begin at the inferior portion of the medulla oblongata because this region has the simplest organization. We then move up to regions of increasing structural and functional complexity.

Embryology of the Brain

The embryonic origin of the brain can help us understand its internal organization. The central nervous system (CNS) begins as a hollow cylinder known as the *neural tube*. At the cephalic portion of the neural tube, three swellings called the **primary brain vesicles** develop. They are named for their relative positions: the *prosencephalon* (prōz-en-SEF-ah-lon; *proso*, forward), or

“forebrain”; the *mesencephalon*, or “midbrain”; and the *rhombencephalon* (rom-ben-SEF-ah-lon), or “hindbrain.”

Table 14-1 summarizes the fates of the primary brain vesicles. The prosencephalon and rhombencephalon are subdivided further, forming **secondary brain vesicles**, while the mesencephalon develops but does not divide:

- The prosencephalon forms the **telencephalon** (tel-en-SEF-a-lon; *telos*, end) and the diencephalon. The telencephalon ultimately forms the cerebrum, and the diencephalon forms the thalamus.
- The walls of the mesencephalon thicken, and the neural tube becomes a relatively narrow passageway, much like the central canal of the spinal cord.
- The portion of the rhombencephalon adjacent to the mesencephalon forms the **metencephalon** (met-en-SEF-ah-lon; *meta*, after). The posterior portion of the metencephalon later becomes the cerebellum, and the anterior portion develops into the pons. The portion of the rhombencephalon closer to the spinal cord forms the **myelencephalon** (mī-el-en-SEF-ah-lon; *myelon*, spinal cord), which becomes the medulla oblongata.

Ventricles of the Brain

During development, the neural tube within the cerebral hemispheres, diencephalon, metencephalon, and medulla oblongata expands to form chambers called **ventricles** (VEN-trih-klz). The *ventricular system* is composed of four ventricles (two lateral ventricles, then the third and fourth ventricles) and their passageways (*interventricular foramen* and *cerebral aqueduct*).

Table 14-1 Development of the Brain

Primary Brain Vesicles (3 weeks)	Secondary Brain Vesicles (6 weeks)	Brain Regions at Birth	Ventricular System
Prosencephalon (Forebrain)	Telencephalon	Cerebrum	Lateral ventricles
	Diencephalon	Diencephalon	Third ventricle
Mesencephalon (Midbrain)	Mesencephalon	Midbrain	Cerebral aqueduct
Rhombencephalon (Hindbrain)	Metencephalon	Cerebellum and Pons	Fourth ventricle
	Myelencephalon	Medulla oblongata	Fourth ventricle

Figure 14-2 Ventricular System. The orientation and extent of the ventricles as they would appear if the brain were transparent.

Each cerebral hemisphere contains a large **lateral ventricle** (Figure 14-2). The *septum pellucidum*, a thin plate of brain tissue, separates the two lateral ventricles. Because there are *two* lateral ventricles, the ventricle in the diencephalon is called the **third ventricle**. The two lateral ventricles are not directly connected, but each communicates with the third ventricle of the diencephalon through an **interventricular foramen**.

The midbrain has a slender canal known as the **cerebral aqueduct**. This passageway connects the third ventricle with the **fourth ventricle**. The superior portion of the fourth ventricle lies between the posterior surface of the pons and the anterior surface of the cerebellum. The fourth ventricle extends into the superior portion of the medulla oblongata. There this ventricle narrows and becomes continuous with the central canal of the spinal cord.

Ependymal cells, a type of neuroglia, line the ventricles. These cells produce *cerebrospinal fluid* (CSF) that fills the ventricles and continuously circulates in the CNS. The CSF passes between the interior and exterior of the CNS through three foramina in the roof of the fourth ventricle. We describe these foramina in Section 14-7.

Checkpoint

1. Name the four major regions of the brain.
2. What brain regions make up the brainstem?
3. Which primary brain vesicle is destined to form the cerebellum, pons, and medulla oblongata?

See the blue Answers tab at the back of the book.

14-2 The brain is protected and supported by the cranial meninges, cerebrospinal fluid, and the blood-brain barrier

Learning Outcome Explain how the brain is protected and supported, and discuss the formation, circulation, and function of cerebrospinal fluid.

The delicate tissues of the brain are protected from physical forces by the bones of the cranium, membranes called the *cranial meninges*, and cerebrospinal fluid. In addition, the nervous tissue of the brain is biochemically isolated from the general circulation by the *blood-brain barrier*.

The Cranial Meninges

The layers that make up the **cranial meninges**—the cranial *dura mater*, *arachnoid mater*, and *pia mater*—are continuous with the spinal meninges. However, the cranial meninges have distinctive anatomical and functional characteristics (Figure 14-3a).

Dura Mater and Dural Folds

The **dura mater** consists of outer and inner fibrous layers. The outer layer is fused to the periosteum of the cranial bones. As a result, there is no epidural space superficial to the dura mater, as occurs along the spinal cord. The outer *periosteal cranial dura* and inner *meningeal cranial dura* are typically fused together.

Figure 14-3 The Relationships among the Brain, Cranium, and Cranial Meninges.

List the maters surrounding the brain from the deepest layer to the most superficial layer.

In several locations, the meningeal cranial dura extends into the cranial cavity, forming a sheet that dips inward and then returns. These inward projections, known as **dural folds**, provide additional stabilization and support to the brain. **Dural venous sinuses** are large collecting veins located within the dural folds. The veins of the brain open into these sinuses, which deliver the venous blood to the veins of the neck. The three largest dural folds are called the *falx cerebri*, the *tentorium cerebelli*, and the *falx cerebelli* (Figure 14-3b):

- The **falx cerebri** (FALKS SER-e-brī; *falx*, sickle shaped) is a fold of dura mater that projects between the cerebral hemispheres in the longitudinal cerebral fissure. Its inferior portions attach anteriorly to the crista galli of the ethmoid

and posteriorly to the *internal occipital crest*, a ridge along the inner surface of the occipital bone. The **superior sagittal sinus** and the **inferior sagittal sinus**, two large dural venous sinuses, lie within this dural fold. The posterior margin of the falx cerebri intersects the tentorium cerebelli.

- The **tentorium cerebelli** (ten-TŌ-rē-um ser-e-BEL-ē; *tentorium*, tent) protects the cerebellum and separates the cerebral hemispheres from the cerebellum. It extends across the cranium at right angles to the falx cerebri. The **transverse sinus** is a paired dural venous sinus that runs along the occipital bone. It allows blood to drain from the back of the head.
- The **falx cerebelli** divides the two cerebellar hemispheres along the midsagittal line inferior to the tentorium cerebelli.

The dura mater may be separated from the next layer of membrane, the arachnoid mater, by a narrow gap called the **subdural space**.

Arachnoid Mater

The **arachnoid mater** is a membrane that resembles a spiderweb. An arachnoid barrier cell layer is attached to the dural border cell layer of the dura mater, and no natural space occurs at this interface. (However, a subdural space may form as a result of trauma, disease, or lack of cerebrospinal fluid, as in a cadaver.) The cranial arachnoid mater covers the brain, providing a smooth surface that does not follow the brain's underlying folds. The **subarachnoid space**, containing cells and fibers of the arachnoid trabeculae, lies between the arachnoid mater and the pia mater.

Pia Mater

The **pia mater** sticks closely to the surface of the brain, anchored by the processes of astrocytes. It also accompanies the branches of cerebral blood vessels as they penetrate the surface of the brain to reach internal structures.

Cerebrospinal Fluid

Cerebrospinal fluid (CSF) surrounds and bathes the exposed surfaces of the CNS. The CSF has several important functions, including:

- **Supporting the Brain.** In essence, the brain is suspended inside the cranium and floats in the CSF. A human brain weighs about 1400 g (3.09 lb) in air, but only about 50 g (1.8 oz) when supported by CSF.
- **Cushioning Delicate Neural Structures.** CSF cushions the brain and spinal cord against physical trauma.

- **Transporting Nutrients, Chemical Messengers, and Wastes.** Except in the areas where CSF is produced, the ependymal cell lining is freely permeable. The CSF is in constant chemical communication with the interstitial fluid that surrounds the neurons and neuroglia of the CNS.

The Formation and Circulation of CSF

A **choroid** (KOR-oyd) **plexus** (*choroeides*, like a membrane; *plexus*, network) is an area within each ventricle that produces CSF. Specialized ependymal cells bearing microvilli and interconnected by tight junctions surround the capillaries of a choroid plexus. The process by which these cells form CSF is shown in step 1 of **Spotlight Figure 14–4**. CSF is a filtrate produced by the fluid leaking out of the capillaries in the choroid plexuses. The ependymal cells then secrete CSF into the ventricles. They also remove wastes from the CSF and adjust its composition over time.

Because free exchange occurs between the interstitial fluid of the brain and the CSF in this way, changes in CNS function can produce changes in the composition of the CSF and vice versa. The differences in composition between CSF and blood plasma (blood with the cellular elements removed) are quite noticeable. For example, blood plasma contains high concentrations of soluble proteins, but the CSF does not. The concentrations of individual ions and the levels of amino acids, lipids, and waste products are also different. As noted in Chapter 13, a *spinal tap* procedure that is done to collect a sample of CSF can provide useful clinical information about CNS injury, infection, or disease.

Steps 2–5 of **Spotlight Figure 14–4** show how the 150 mL of CSF is circulated in the CNS. If the normal circulation or resorption of CSF is interrupted, a variety of clinical problems

Clinical Note Epidural and Subdural Hemorrhages

A severe head injury may damage meningeal blood vessels and cause bleeding into the cranial cavity. The most serious cases involve an arterial break because arterial blood pressure is relatively high. If blood is forced between the dura mater and the skull, the condition is known as an **epidural hemorrhage** (HEM-ō-raj). The elevated fluid pressure then distorts the underlying tissues of the brain. The individual loses consciousness for a period lasting from minutes to hours after the injury, and death follows in untreated cases. An epidural hemorrhage involving a damaged vein does not produce massive symptoms immediately. The individual may not have neurological problems for hours, days, or even weeks after the original injury. As a result, the problem may not be noticed until the nervous tissue has been severely

damaged. Epidural hemorrhages are rare, occurring in less than 1% of head injuries. However, the mortality rate is 100% in untreated cases and over 50% even after the blood pool has been removed and the damaged vessels have been closed.

A **subdural hemorrhage** is bleeding between the dura mater and the arachnoid mater. Subdural hemorrhages are twice as common as epidural hemorrhages. Small veins between the arachnoid mater and dura mater or one of the dural venous sinuses cause the bleeding. Because the venous blood pressure in a subdural hemorrhage is lower than that in an arterial epidural hemorrhage, the distortion produced is gradual. The effects on brain function can be quite variable and difficult to diagnose.

Cerebrospinal fluid (CSF) completely surrounds and bathes the exposed surfaces of the CNS. The CSF has three important functions:

- Supporting the brain.
- Cushioning the brain and spinal cord against physical trauma.
- Transporting nutrients, chemical messengers, and wastes.

1

The choroid plexus produces and maintains CSF. Two extensive folds of the choroid plexus originate in the roof of the third ventricle and extend through the interventricular foramina. These folds cover the floors of the lateral ventricles. In the inferior brainstem, a region of the choroid plexus in the roof of the fourth ventricle projects between the cerebellum and the pons.

Choroid plexus of third ventricle

2

The CSF circulates from the choroid plexus through the ventricles and fills the central canal of the spinal cord. As it circulates, materials diffuse between the CSF and the interstitial fluid of the CNS across the ependymal cells.

3

The CSF reaches the subarachnoid space through two lateral apertures and a single median aperture in the roof of the fourth ventricle.

4

Cerebrospinal fluid then flows through the subarachnoid space surrounding the brain, spinal cord, and cauda equina.

5

Fingerlike extensions of the arachnoid membrane, called the arachnoid villi, penetrate the meningeal layer of the dura mater and extend into the superior sagittal sinus. In adults, these extensions form large arachnoid granulations. CSF is absorbed into the venous circulation at the arachnoid granulations.

The choroid plexus produces CSF at a rate of about 500 mL, or 2.1 cups, per day. The total volume of CSF at any moment is approximately 150 mL. The entire volume of CSF is replaced about every 8 hours. Despite this rapid turnover, the composition of CSF is closely regulated, and the rate of removal normally keeps pace with the rate of production.

may appear. For example, a problem with the resorption of CSF in infancy causes *hydrocephalus*, or “water on the brain.” Infants with this condition have enormously expanded skulls due to the presence of an abnormally large volume of CSF. In adults, a failure of resorption or a blockage of CSF circulation can distort and damage the brain.

The Protective Function of the Cranial Meninges and CSF

The overall shape of the brain corresponds to that of the cranial cavity (**Figure 14–3a**). The cranial bones physically protect the brain by cradling it, but they also pose a threat to its safety that is countered by the cranial meninges and the CSF. The brain and cranium are like a person driving a car: If the car hits a tree, the car protects the driver from contact with the tree, but serious injury will occur unless a seat belt or airbag protects the driver from contact with the car. The tough, fibrous dural folds act like seat belts that hold the brain in position and restrain it from being damaged by contact with the hard cranium. The cerebrospinal fluid in the subarachnoid space acts like an airbag by cushioning the brain against sudden jolts.

Cranial trauma is a head injury resulting from impact with another object. Each year in the United States, about 8 million cases of cranial trauma occur, but only one case in eight results in serious brain damage. The percentage is relatively low because the cranial meninges and CSF are so effective in protecting the brain.

The Blood Supply to the Brain

The brain, with its billions of neurons, is an extremely active organ with a continuous demand for nutrients and oxygen. However, as noted in Chapter 12, neurons have no energy reserves in the form of carbohydrates or lipids. Neurons also have no equivalent to myoglobin to store oxygen. Therefore, an extensive network of blood vessels meets these demands.

Arterial blood reaches the brain through the *internal carotid arteries* and the *vertebral arteries*. Most of the venous blood from the brain leaves the cranium in the *internal jugular veins*, which drain the dural venous sinuses.

Cerebrovascular diseases are cardiovascular disorders that interfere with the normal blood supply to the brain. The distribution of the vessel involved determines the signs and symptoms. The degree of oxygen or nutrient starvation determines their severity. A **cerebrovascular accident (CVA)**, or *stroke*, occurs when the blood supply to a portion of the brain is shut off. Affected neurons begin to die in a matter of minutes.

The Blood-Brain Barrier

Nervous tissue in the CNS is isolated from the general circulation by the **blood-brain barrier (BBB)**. This barrier is formed

by capillary endothelial cells that are extensively interconnected by tight junctions. These junctions prevent materials from diffusing between endothelial cells. In general, only lipid-soluble compounds (including carbon dioxide; oxygen; ammonia; lipids, such as steroids or prostaglandins; and small alcohols) can diffuse across the membranes of endothelial cells into the interstitial fluid of the brain and spinal cord. Water and ions must pass through channels in the apical and basal surfaces of plasma membranes. Larger, water-soluble compounds can cross the capillary walls only by active or passive transport.

Astrocytes are critical components of the blood-brain barrier (**Figure 12–4**). These neuroglia play a key supporting role in the BBB because they release chemicals that lead to the formation of strong tight junctions and control the permeability of the endothelium to various substances, such as nutrients and ions. Astrocytes are in close contact with CNS capillaries. The processes of astrocytes cover the outer surfaces of the endothelial cells. If the astrocytes are damaged or stop stimulating the endothelial cells, the blood-brain barrier disappears.

The choroid plexus is not part of the nervous tissue of the brain, so no astrocytes are in contact with the endothelial cells there. Substances do not have free access to the CNS, however, because specialized ependymal cells create a **blood-CSF barrier**. These cells, also interconnected by tight junctions, surround the capillaries of the choroid plexus.

Transport across the blood-brain barrier and blood-CSF barrier is selective and directional. Even the passage of small ions, such as sodium, hydrogen, potassium, or chloride, is controlled. As a result, the pH and concentrations of sodium, potassium, calcium, and magnesium ions in the blood and CSF are different. Some organic compounds are readily transported, and others cross only in very small amounts.

Neurons have a constant need for glucose that must be met no matter the glucose concentrations in the blood and interstitial fluid. Even when the circulating glucose level is low, endothelial cells continue to transport glucose from the blood to the interstitial fluid of the brain. In contrast, only trace amounts of circulating *neurohormones* (chemical messengers released by neurons into the bloodstream), such as norepinephrine, epinephrine, dopamine, and serotonin, pass into the interstitial fluid or CSF of the brain. This limitation is important, because the entry of these neurotransmitters from the bloodstream (where their concentrations can be relatively high) could result in the uncontrolled stimulation of neurons throughout the brain.

The blood-brain barrier remains intact throughout the CNS except in small areas known as *circumventricular organs* (CVOs), which have fenestrated capillaries (blood vessels with ultramicroscopic pores). Because they are outside the blood-brain barrier, they provide a direct link between the CNS and the peripheral blood and they play a role in neuroendocrine function. In summary, these noteworthy exceptions include:

- Portions of the hypothalamus, where the capillary endothelium is extremely permeable. This permeability exposes hypothalamic nuclei to circulating hormones and permits hypothalamic hormones to diffuse into the circulation.
- Capillaries in the posterior lobe of the pituitary gland, which is continuous with the floor of the hypothalamus. At this site, the hormones antidiuretic hormone and oxytocin, produced by hypothalamic neurons, are released into the circulation.
- Capillaries in the *pineal gland*. This endocrine gland is located on the posterior, superior surface of the diencephalon. The capillary permeability allows pineal secretions to enter the general circulation.
- Capillaries at a choroid plexus. The capillary characteristics of the blood-brain barrier are lost there, but the transport activities of specialized ependymal cells in the choroid plexuses maintain the blood-CSF barrier.

Physicians must sometimes get specific compounds into the interstitial fluid of the brain to fight CNS infections or to treat other neurological disorders. To do this, they must understand the limitations of the blood-brain barrier and blood-CSF barrier. For example, when considering possible treatments, the antibiotic *tetracycline* is not used to treat meningitis or other CNS infections because this drug cannot cross the barriers to reach the brain. In contrast, *sulfisoxazole* and *sulfadiazine* enter the CNS very rapidly. Sometimes, chemotherapeutic drugs or imaging dyes may be injected directly into the CSF by lumbar puncture.

14

✓ Checkpoint

4. From superficial to deep, name the layers that make up the cranial meninges.
5. What would happen if the normal circulation or resorption of CSF were blocked?
6. How would a decreased rate of diffusion across the arachnoid granulations affect the volume of CSF in the ventricles?
7. Many water-soluble molecules that are abundant in the blood occur in small amounts or not at all in the CSF of the brain. Why?

See the blue Answers tab at the back of the book.

14-3 Brainstem: The medulla oblongata relays signals between the rest of the brain and the spinal cord

Learning Outcome Describe the anatomical differences between the medulla oblongata and the spinal cord and identify the main components and functions of the medulla oblongata.

The **medulla oblongata** is the most inferior of the brainstem regions. **Figure 14-5** shows the position of the medulla oblongata in relation to the other components of the brainstem

and the diencephalon. It also illustrates the attachment sites for 11 of the 12 pairs of cranial nerves. The individual cranial nerves are identified by capital letters CN followed by a Roman numeral (I–XII). (We discuss the full names and functions of these nerves in a later section.)

In sectional view, the inferior portion of the medulla oblongata resembles the spinal cord, with a small central canal. However, the gray matter and white matter organization is more complex. As the central canal travels superiorly through the medulla oblongata, the canal opens to become the fourth ventricle, and the similarity to the spinal cord fades.

The medulla oblongata includes three groups of nuclei that we introduce here and meet again in later chapters (**Figure 14-6**). First are nuclei and processing centers that control visceral functions. The medulla oblongata is a center for the coordination of complex autonomic reflexes. Second are sensory and motor nuclei of the CNS. Third are relay stations that move all communication between the brain and spinal cord by tracts that ascend or descend through the medulla oblongata.

- **Reflex Centers: Autonomic and Reflex Activity.** The **reticular formation** is a closely intermingled mass of gray and white matter that contains embedded nuclei. It extends throughout the central core of the medulla oblongata and into the diencephalon and plays a role in autonomic (breathing, blood pressure, and thermoregulation) and endocrine functions as well as body posture, skeletomuscular reflex activity, alertness, and sleep.

There are two major groups of reflex centers in the medulla oblongata, cardiovascular and respiratory. The **cardiovascular centers** adjust the heart rate, the strength of cardiac contractions, and the flow of blood through peripheral tissues. (Functionally, the cardiovascular centers are subdivided into *cardiac* and *vasomotor centers*, but their anatomical boundaries are difficult to determine.) The **respiratory rhythmicity centers** set the basic pace for respiratory movements. Their activity is regulated by inputs from the respiratory centers of the pons.

- **Sensory and Motor Nuclei of Cranial Nerves.** The medulla oblongata contains sensory and motor nuclei associated with five of the cranial nerves (VIII, IX, X, XI, and XII). These cranial nerves provide motor commands to muscles of the pharynx, neck, and back as well as to the visceral organs of the thoracic and peritoneal cavities. Cranial nerve VIII carries sensory information from receptors in the internal ear to the vestibular nuclei (involved with balance) and cochlear nuclei (involved with hearing), which extend from the pons into the medulla oblongata.
- **Relay Stations along Sensory and Motor Pathways.** The **gracile nucleus** and the **cuneate nucleus** pass somatic sensory

Figure 14-5 The Diencephalon and Brainstem. The brainstem is made up of the medulla oblongata, pons, and midbrain.

information to the thalamus. Tracts leaving these brainstem nuclei cross to the opposite side of the brain before reaching their destinations. This crossing over is called a *decussation* (dē-kuh-SĀ-shun; *decussatio*, crossing over), and the site is the **decussation of pyramids**.

In addition, a few important paired nuclei are found in the medulla oblongata. The **solitary nuclei** (*nuclei of solitary tract*) are the visceral sensory nuclei, receiving information from the spinal and cranial nerves. This information is integrated and forwarded to other autonomic centers in the medulla oblongata and elsewhere.

The **inferior olivary complex** consists of three nuclei that collectively form the inferior olivary nucleus. They relay information to the cerebellar cortex about somatic motor commands as they are issued by motor centers at higher levels. The bulk of the olivary nuclei creates the **olives**, prominent olive-shaped bulges along the ventrolateral surface of the medulla oblongata.

Note that **Figure 14–6** also contains a table that summarizes the major components of the medulla oblongata and their functions.

Figure 14–6 The Medulla Oblongata.

b Posterolateral view

The Medulla Oblongata

Region/Nucleus	Function
GRAY MATTER	
Inferior olivary complex	Relays information from the red nucleus, other midbrain centers, and the cerebral cortex to the cerebellum
Reflex centers	
Cardiovascular centers	Regulate heart rate and force of contraction
Respiratory rhythmicity centers	Set the basic pace of respiratory movements
Gracile nucleus	Relay somatic information to the thalamus
Cuneate nucleus	
Other nuclei/centers: Cranial nerves VIII (in part), IX, X, XI (in part), and XII	Sensory and motor nuclei of five cranial nerves Nuclei relay ascending information from the spinal cord to higher centers
Reticular formation	Contains nuclei and centers that regulate vital autonomic functions; extends into the pons and midbrain
WHITE MATTER	
Ascending and descending tracts within funiculi	Link the brain with the spinal cord

✓ Checkpoint

8. Identify the components of the medulla oblongata that are responsible for relaying somatic sensory information to the thalamus.
9. The medulla oblongata is one of the smallest sections of the brain, yet damage there can cause death, whereas similar damage in the cerebrum might go unnoticed. Why?

See the blue Answers tab at the back of the book.

14-4 Brainstem: The pons contains nuclei that process and tracts that relay sensory and motor information

Learning Outcome List the main components of the pons and specify the functions of each.

The **pons** links the cerebellum with the midbrain, diencephalon, cerebrum, and spinal cord. **Figure 14-5** shows the spatial relationship of the pons with these structures.

Important features and regions of the pons are shown in **Figure 14-7**, along with a summary of its major components and their functions. The pons contains four groups of components:

- **Sensory and Motor Nuclei of Cranial Nerves.** These cranial nerves (V, VI, VII, and VIII) innervate the jaw muscles, the anterior surface of the face, one of the extrinsic eye muscles (the lateral rectus), and the sense organs of the internal ear (the vestibular and cochlear nuclei).

- **Nuclei Involved with the Control of Respiration.** Research on laboratory animals has identified regions in the medulla and pons, known as *centers*, that appear to modify breathing activities. Two pontine centers, the *apneustic* (ap-NŪS-tik) *center* located in the middle or lower pons and the *pneumotaxic* (nū-mō-TAK-sik) *center* located in the pons, process information originating in the respiratory rhythmicity centers of the medulla oblongata. These centers are further discussed in Chapter 23.
- **Nuclei and Tracts That Process and Relay Information Sent to or from the Cerebellum.** The pons links the cerebellum with the brainstem, cerebrum, and spinal cord.
- **Ascending, Descending, and Transverse Pontine Fibers.** Longitudinal tracts interconnect other portions of the CNS. Tracts of the cerebellum (middle cerebellar peduncles) are connected to the **transverse pontine fibers**, which cross the anterior surface of the pons. These fibers are axons that link nuclei of the pons (*pontine nuclei*) with the cerebellum of the opposite side.

✓ Checkpoint

10. Name the four groups of components found in the pons.
11. If the respiratory centers of the pons were damaged, what respiratory controls might be lost?

See the blue Answers tab at the back of the book.

Figure 14-7 The Pons.

The Pons

Region/Nucleus	Function
WHITE MATTER	
Descending tracts	Carry motor commands from higher centers to nuclei of cranial or spinal nerves
Ascending tracts	Carry sensory information from brainstem nuclei to the thalamus
Transverse pontine fibers	Interconnect cerebellar hemispheres
GRAY MATTER	
Apneustic and pneumotaxic centers	Adjust activities of the respiratory rhythmicity centers in the medulla oblongata
Reticular formation	Automatic processing of incoming sensations and outgoing motor commands
Nuclei of cranial nerves V, VI, VII, and VIII (in part)	Relay sensory information and issue somatic motor commands
Other nuclei/relay centers	Relay sensory and motor information to the cerebellum

14-5 Brainstem: The midbrain regulates visual and auditory reflexes and controls alertness

Learning Outcome List the main components of the midbrain and specify the functions of each.

Figure 14-8a shows the external anatomy of the midbrain and lists its major nuclei. The **tectum**, or roof of the midbrain, is the region posterior (dorsal) to the cerebral aqueduct. It contains two pairs of sensory nuclei known collectively as the **corpora quadrigemina** (KOR-pōr-uh kwad-rih-JEM-ih-nuh; **Figure 14-8b**). These nuclei, the *superior* and *inferior colliculi*, process visual and auditory sensations. Each **superior colliculus** (ko-LIK-ū-lus; *colliculus*, hill) receives visual inputs from the lateral geniculate body of the thalamus on that side. Each **inferior colliculus** receives auditory input from nuclei in the medulla oblongata and pons. Some of this information may be forwarded to the medial geniculate body of the thalamus on the same side. The superior colliculi control the reflex movements of the eyes, head, and neck in response to visual stimuli, such as a bright light. The inferior colliculi control reflex movements of the head, neck, and trunk in response to auditory stimuli, such as a loud noise.

The area anterior to the cerebral aqueduct is called the **tegmentum**. On each side, the tegmentum contains a *red nucleus* and the *substantia nigra* (**Figure 14-8c**). The **red nucleus** contains numerous blood vessels, which give it a rich red color when freshly dissected. This nucleus receives information from the cerebrum and cerebellum and issues subconscious motor commands that affect upper limb position and background muscle tone. The **substantia nigra** (NĪ-gruh; *nigra*, black) is the largest midbrain nucleus. It lies lateral to the red nucleus. The neurons of the substantia nigra release the neurotransmitter *dopamine*. The gray matter in this region contains darkly pigmented cells, giving it a blackish color. The pigment is melanin, and here it is a by-product of dopamine synthesis. The substantia nigra inhibits activity of the basal nuclei in the cerebrum. The *basal nuclei* are involved in the subconscious control of muscle tone and learned movements. As discussed in upcoming Section 14-9, *Parkinson's disease* is characterized by the loss of neuronal activity in the substantia nigra.

The nerve fiber bundles on the ventrolateral surfaces of the midbrain (**Figure 14-8b,c**) are the **cerebral peduncles** (PEH-dung-kelz; *peduncles*, little feet). They contain (1) descending fibers that go to the cerebellum by way of the pons and (2) descending fibers that carry voluntary motor commands issued by the cerebral hemispheres.

Although the reticular formation extends the length of the brainstem, its headquarters resides in the midbrain. The midbrain also contains the *reticular activating system* (RAS), a specialized component of the reticular formation. Stimulation of the RAS makes a person more alert and attentive; damage to the RAS produces unconsciousness. The role of the RAS in maintaining consciousness is discussed in Chapter 16.

✓ Checkpoint

- Identify the sensory nuclei within the corpora quadrigemina.
- Which area of the midbrain controls reflexive movements of the eyes, head, and neck in response to visual stimuli?

See the blue Answers tab at the back of the book.

14-6 The cerebellum coordinates reflexive and learned patterns of muscular activity at the subconscious level

Learning Outcome List the main components of the cerebellum and specify the functions of each.

The cerebellum is an automatic processing and coordination center for patterns of muscular activity. Let's look at its structure and function.

Structure of the Cerebellum

The cerebellum has a complex, highly convoluted surface composed of gray matter called the **cerebellar cortex** (**Figure 14-9a**). The **folia** (FŌ-lē-uh; leaves), or folds of the cerebellum surface, are less prominent than the folds in the surfaces of the cerebral hemispheres. The **primary fissure** separates the **anterior** and **posterior lobes**. Along the midline, a narrow band of cortex known as the **vermis** separates the **cerebellar hemispheres**. The slender **flocculonodular lobe** (flok-yū-lō-NOD-yū-lar) lies between the roof of the fourth ventricle and the cerebellar hemispheres and vermis (**Figure 14-9b**).

The cerebellar cortex contains a layer of large, highly branched neuron cell bodies called the **Purkinje** (pur-KIN-jē) **cell layer**. The extensive dendrites of each Purkinje cell receive input from up to 200,000 synapses—more than any other type of brain cell. The internal white matter of the cerebellum forms a branching array that in sectional view resembles a tree. Anatomists call it the **arbor vitae** (VĒ-tā), or “tree of life” (**Figure 14-9b**). It connects the cerebellar cortex and nuclei with the tracts of white matter that form the **cerebellar peduncles**, which we discuss in more detail soon.

Functions of the Cerebellum

The cerebellum has two primary functions:

- Adjusting the Postural Muscles of the Body.** The cerebellum coordinates rapid, automatic adjustments that maintain balance and equilibrium. It makes these alterations in muscle tone and position by modifying the activities of motor centers in the brainstem.

Figure 14–8 The Midbrain.

a A posterior view. The underlying nuclei are colored only on the right.

The Midbrain

Region/Nuclei	Function
GRAY MATTER	
Tectum (roof)	
Superior colliculi	Integrate visual information with other sensory input; initiate reflex responses to visual stimuli
Inferior colliculi	Relay auditory information to medial geniculate nuclei; initiate reflex responses to auditory stimuli
Walls and floor	
Substantia nigra	Regulates activity in the basal nuclei
Red nucleus	Subconscious control of upper limb position and background muscle tone
Reticular formation	Automatic processing of incoming sensations and outgoing motor commands; can initiate involuntary motor responses to stimuli; helps maintain consciousness
Other nuclei/centers	Nuclei associated with cranial nerves III and IV
WHITE MATTER	
Cerebral peduncles	Connect primary motor cortex with motor neurons in brain and spinal cord; carry ascending sensory information to thalamus

b Posterior view of a cadaver dissection of the diencephalon and brainstem.

c A superior view of a transverse section at the level of the midbrain.

- **Programming and Fine-Tuning Movements Controlled at the Conscious and Subconscious Levels.** The cerebellum refines learned movement patterns, such as riding a bicycle or playing the piano. It performs this function indirectly by regulating activity along motor pathways at the cerebral cortex, basal nuclei, and motor centers in the brainstem. The cerebellum compares the motor commands with *proprioceptive* information (position sense) and stimulates any adjustments needed to make the movement smooth.

The cerebellum receives proprioceptive information from the spinal cord and monitors all proprioceptive, visual, tactile, balance, and auditory sensations received by the brain. Most axons that carry sensory information do not synapse in the cerebellar nuclei but pass through the deeper layers of the cerebellum on their way to the Purkinje cells of the cerebellar cortex. Information about the motor commands issued at the conscious and subconscious levels reaches the Purkinje cells indirectly, after being relayed by nuclei in the pons or by the **cerebellar nuclei** embedded within the arbor vitae.

Figure 14–9 The Cerebellum.

a The posterior, superior surface of the cerebellum, showing major anatomical landmarks and regions

b A sectional view of the cerebellum, showing the arrangement of gray matter and white matter

The Cerebellum

Region/Nuclei	Function
GRAY MATTER	
Cerebellar cortex	Involuntary coordination and control of ongoing body movements
Cerebellar nuclei	Involuntary coordination and control of ongoing body movements
WHITE MATTER	
Arbor vitae	Connects cerebellar cortex and nuclei with cerebellar peduncles
Cerebellar peduncles	
Superior	Link cerebellum with midbrain, diencephalon, and cerebrum
Middle	Carry communications between the cerebellum and pons
Inferior	Link the cerebellum with the medulla oblongata and spinal cord
Transverse pontine fibers	Interconnect pontine nuclei with the opposite cerebellar hemisphere

What makes up the gray matter in the cerebellum?

Tracts that link the cerebellum with the brainstem, cerebrum, and spinal cord leave the cerebellar hemispheres as the *superior, middle, and inferior cerebellar peduncles*:

- The **superior cerebellar peduncles** link the cerebellum with nuclei in the midbrain, diencephalon, and cerebrum.
- The **middle cerebellar peduncles** are connected to the transverse pontine fibers. The middle cerebellar peduncles also connect the cerebellar hemispheres with sensory and motor nuclei in the pons.
- The **inferior cerebellar peduncles** communicate between the cerebellum and nuclei in the medulla oblongata and carry ascending and descending cerebellar tracts from the spinal cord.

The cerebellum can be permanently damaged by trauma or stroke. Drugs such as alcohol can also temporarily affect it. The result is **ataxia** (ah-TAK-sē-uh; *ataxia*, lack of order), a disturbance in muscular coordination. In severe ataxia, the individual cannot sit or stand without assistance.

Checkpoint

14. Identify the components of the cerebellar gray matter.
15. What part of the brain contains the arbor vitae? What is its function?

See the blue Answers tab at the back of the book.

14-7 The diencephalon integrates sensory information with motor output at the subconscious level

Learning Outcome List the main components of the diencephalon, and specify the functions of each.

The diencephalon is a division of the brain that consists of the epithalamus, thalamus, and hypothalamus. Look at **Figure 14-5** to review its position and its relationship to landmarks on the brainstem.

The *epithalamus* is the roof of the diencephalon superior to the third ventricle. The anterior portion of the epithalamus contains an extensive area of choroid plexus that extends through the interventricular foramina into the lateral ventricles. The posterior portion of the epithalamus contains the **pineal** (PIN-ē-ul) **gland** (**Figure 14-5c,d**), an endocrine structure that secretes the hormone **melatonin**. Melatonin is important in regulating day–night cycles and reproductive functions. (The role of melatonin is described in Chapter 18.)

Most of the nervous tissue in the diencephalon is concentrated in the *thalamus*, which forms the lateral walls, and the *hypothalamus*, which forms the floor. The rest of this section looks at the structure and critical functions of the thalamus and hypothalamus.

The Thalamus

On each side of the diencephalon, the **thalamus** is the final relay point for sensory information ascending to the cerebral cortex. Ascending sensory information from the spinal cord and cranial nerves (other than the olfactory tract) synapses in a nucleus in the left side or right side of the thalamus before reaching the cerebral cortex and our conscious awareness. It acts as a filter, passing on only a small portion of the arriving sensory information. The thalamus also coordinates the activities of the basal nuclei (which we discuss shortly) and the cerebral cortex by relaying information between them.

Structure of the Thalamus

The third ventricle separates the thalamus into left and right sides. Each side consists of a rounded mass of groups of *thalamic nuclei* (**Figure 14-10**). Viewed in a midsagittal section through the brain (**Figure 14-11a,b**), each side of the thalamus extends from the anterior commissure to the inferior base of the pineal gland. A projection of gray matter called an **interthalamic adhesion** extends into the ventricle from the thalamus on each side, but no fibers cross the midline (**Figure 14-11b**).

Functions of Thalamic Nuclei

The thalamic nuclei deal primarily with the relay of sensory information to the basal nuclei and cerebral cortex. Five major groups of thalamic nuclei are shown in **Figure 14-10b** and listed in **Table 14-2**. They are the anterior, medial, ventral, and dorsal nuclei, and the lateral and medial geniculate bodies.

- The **anterior nuclei of thalamus** are part of the *limbic system*. This system affects emotional states and integrates sensory information. It is discussed in Section 14-8.
- The **medial nuclei of thalamus** provide an awareness of emotional states by connecting emotional centers in the hypothalamus with the *frontal lobes* of the cerebral hemispheres. The medial nuclei also receive and relay sensory information from other portions of the thalamus.
- The **ventral nuclei of thalamus** relay information from the basal nuclei of the cerebrum and the cerebellum to somatic motor areas of the cerebral cortex. Ventral group nuclei also relay sensory information about touch, pressure, pain, temperature, and proprioception (position) to the sensory areas of the cerebral cortex.
- The **dorsal nuclei of thalamus** include the lateral dorsal nucleus and pulvinar nuclei. The **pulvinar** is the expanded region of the thalamus overlying the geniculate bodies. These dorsal nuclei integrate sensory information for sending signals (projecting) to the cerebral cortex.

Figure 14–10 The Thalamus.

- The **lateral geniculate** (je-NIK-yū-lāt) **body** receives visual information over the *optic tract*, which originates at the eyes. The output of the **lateral geniculate body** goes to the *occipital lobes* of the cerebral hemispheres and to the midbrain. The **medial geniculate body** relays auditory information to the appropriate area of the cerebral cortex from specialized receptors of the internal ear. This body forms feedback loops with the limbic system and the *parietal lobes* of the cerebral hemispheres.

The Hypothalamus

The hypothalamus contains centers involved with emotions and visceral processes that affect the cerebrum as well as

Table 14–2 The Thalamus

Nuclei/Body	Function
Anterior nuclei	Part of the limbic system
Medial nuclei	Integrate sensory information for projection to the frontal lobes
Ventral nuclei	Project sensory information to the primary sensory cortex; relay information from cerebellum and basal nuclei to motor area of cerebral cortex
Dorsal nuclei	
Lateral dorsal nucleus	Projects information to parietal, occipitoparietal, and temporal cortex; may play a role in memory
Pulvinar nuclei	Integrate sensory information for projection to association areas of cerebral cortex
Lateral geniculate body	Projects visual information to the visual cortex; integrates sensory information and influences emotional states
Medial geniculate body	Projects auditory information to the auditory cortex; integrates sensory information and influences emotional states

components of the brainstem. It also controls a variety of autonomic functions and forms the link between the nervous and endocrine systems.

Structure of the Hypothalamus

The **hypothalamus** extends from the area superior to the *optic chiasm* (the location where axons within the optic nerves arrive at the brain and cross over) to the posterior margins of the **mammillary** (*mammilla*, nipple) **bodies** (Figure 14–11a). Immediately posterior to the optic chiasm, a narrow stalk called the **infundibulum** (in-fun-DIB-ū-lum; *infundibulum*, funnel) extends inferiorly, connecting the floor of the hypothalamus to the pituitary gland (Figure 14–11b). The floor of the hypothalamus between the infundibulum and the mammillary bodies is the **tuber cinereum** (TŪ-ber si-nir-Ē-um; *tuber*, swelling).

Functions of the Hypothalamus

The hypothalamus contains important nuclei that function as control and integrative centers in addition to those associated with the limbic system. These centers are shown in Figure 14–11b, along with a summary of their functions.

Hypothalamic centers may be stimulated by (1) sensory information from the cerebrum, brainstem, and spinal cord; (2) changes in the compositions of the CSF and interstitial fluid; or (3) chemical stimuli in the circulating blood that move rapidly across highly permeable capillaries to enter the hypothalamus (where there is no blood-brain barrier).

Figure 14–11 The Hypothalamus in Sagittal Section.

a The hypothalamus and adjacent portions of the brain

Figure 14–12 is a diagram of the hypothalamus and its connections. It shows the hypothalamus at the center, with the thalamus above it, the mid-brain below it, and the pituitary gland at the bottom. The infundibulum is shown connecting the hypothalamus to the pituitary gland. The optic chiasm is shown where the optic nerves cross. The tuber cinereum is shown as a part of the hypothalamus. The diagram is color-coded to show different regions and nuclei. Labels include: Interthalamic adhesion, Thalamus, Hypothalamus, Tuber cinereum, Optic chiasm, Infundibulum, Pituitary gland, Mid-brain, and Pons.

The Hypothalamus

Region/Nuclei	Function
Paraventricular nucleus	Secretes oxytocin; stimulates smooth muscle contractions in uterus and mammary glands
Pre-optic area	Regulates body temperature by control of autonomic centers in the medulla oblongata
Autonomic centers	Control heart rate and blood pressure by regulation of autonomic centers in the medulla oblongata
Sympathetic	
Parasympathetic	
Lateral tuberal nuclei	Produce inhibitory and releasing hormones that control endocrine cells of the anterior lobe of the pituitary gland (adenohypophysis)
Mammillary bodies	Control feeding reflexes (licking, swallowing)
Suprachiasmatic nucleus	Regulates daily (circadian) rhythms
Supra-optic nucleus	Secretes antidiuretic hormone; restricts water loss by the kidneys

b A diagram of the hypothalamus, showing the locations and functions of major nuclei and centers

The hypothalamus performs the following functions:

- **Secretion of Two Hormones.** The hypothalamus secretes *antidiuretic hormone* (ADH, also called vasopressin) and *oxytocin* (ok-sih-TOH-sin). The **supra-optic nucleus** produces ADH, which restricts water loss by the kidneys. The **paraventricular nucleus** produces oxytocin, which stimulates smooth muscle contractions in the uterus and mammary glands of females and the prostate of males. These hormones are transported along axons that pass through the infundibulum to the posterior lobe of the pituitary gland. There the hormones are released into the blood for distribution throughout the body.
- **Regulation of Body Temperature.** The **pre-optic area** of the hypothalamus is responsible for thermoregulation. It coordinates the activities of other CNS centers and regulates other physiological systems to maintain normal body temperature. If body temperature falls, the preoptic area communicates with the vasomotor center, an autonomic center in the medulla oblongata that controls blood flow by regulating the diameter of peripheral blood vessels. In response, the vasomotor center decreases the blood supply to the skin, reducing the rate of heat loss.
- **Control of Autonomic Function.** The hypothalamus adjusts and coordinates the activities of autonomic centers in the pons and medulla oblongata that regulate heart rate, blood pressure, respiration, and digestive functions.
- **Coordination between Voluntary and Autonomic Functions.** When a person thinks about a dangerous or stressful situation, their heart rate and respiratory rate go up as their body prepares for an emergency. The hypothalamus makes these autonomic adjustments.
- **Coordination of Activities of the Nervous and Endocrine Systems.** The hypothalamus coordinates neural and endocrine activities by inhibiting or stimulating endocrine cells in the pituitary gland through the production of *regulatory hormones*. These hormones are produced at the tuber cinereum. They are released into local capillaries for transport to the anterior lobe of the pituitary gland.
- **Regulation of Circadian Rhythms.** The **suprachiasmatic nucleus** (sup-rah-kī-az-MAT-ik) coordinates daily cycles of activity that are linked to the 24-hour day–night cycle. This nucleus receives input from the retina of the eye. The output of this nucleus adjusts the activities of other hypothalamic nuclei, the pineal gland, and the reticular formation.
- **Subconscious Control of Skeletal Muscle Contractions.** The hypothalamus directs somatic motor patterns associated with rage, pleasure, pain, and sexual arousal by stimulating centers in other portions of the brain. For example,

hypothalamic centers control the changes in facial expression that accompany rage and reflexive movements associated with sexual activity.

- **Production of Emotions and Behavioral Drives.** Specific hypothalamic centers produce sensations that lead to conscious or subconscious changes in behavior. For example, stimulation of the **feeding center** produces the sensation of hunger. Stimulation of the **thirst center** produces the sensation of thirst. The **satiety** (sah-TĪ-eh-tē) **center** is the region that regulates food intake. These unfocused “impressions” originating in the hypothalamus are called **drives**. The conscious sensations are only part of the hypothalamic response. For instance, the thirst center also orders the release of ADH by neurons in the supra-optic nucleus.

14-8 The limbic system is a group of nuclei and tracts that functions in emotion, motivation, and memory

Learning Outcome Identify the main components of the limbic system and specify the locations and functions of each.

The **limbic system** is a functional grouping rather than an anatomical (structural) one. Functions of the limbic system include (1) establishing emotional states; (2) linking the conscious, intellectual functions of the cerebral cortex with the unconscious and autonomic functions of the brainstem; and (3) facilitating memory storage and retrieval. The cerebral cortex enables a person to perform complex tasks, but it is largely the limbic system that makes them *want* to do them. For this reason, the limbic system is also known as the *motivational system*.

Figure 14-12 shows the major parts of the limbic system, which includes nuclei and tracts along the border (*limbus*, edge) between the cerebrum and diencephalon. Let’s look at the cerebral, diencephalic, and other components of this system in turn.

The **limbic lobe** of the cerebral hemisphere consists of the superficial folds, or gyri, and underlying structures adjacent to the diencephalon. The gyri curve along the *corpus callosum*, a fiber tract that links the two cerebral hemispheres. The gyri then continue to the medial surface of the cerebrum lateral to the diencephalon (**Figure 14-12a**). There are three gyri in

the limbic lobe. The **cingulate** (SIN-gyū-lāt) **gyrus** (*cingulum*, belt) sits superior to the corpus callosum. The **dentate gyrus** and the **parahippocampal** (pah-rah-hip-ō-KAM-pal) **gyrus** form the posterior and inferior portions of the limbic lobe (**Figure 14-12b**).

These gyri conceal the **hippocampus**, a nucleus inferior to the floor of the lateral ventricle. To early anatomists, this structure resembled a sea horse (*hippocampus*) when removed from the brain. This nucleus is important in learning, especially in the storage and retrieval of new long-term memories.

Another cerebral nucleus is the **amygdaloid** (ah-MIG-duh-loyd; *amygdale*, almond) **body**, commonly referred to as the *amygdala* (**Figure 14-12b**). It appears to act as an interface between the limbic system, the cerebrum, and various sensory systems. It plays a role in regulating heart rate, in responding to fear and anxiety as well as controlling the “fight or flight” response by the sympathetic division of the autonomic nervous system (ANS), and in linking emotions with specific memories.

The **fornix** (FOR-niks, arch) is a tract of cerebral white matter that connects the hippocampus with the hypothalamus

Figure 14-12 The Limbic System.

(Figure 14-12b). From the hippocampus, the fornix curves medially, meeting its counterpart from the opposing hemisphere. The fornix proceeds anteriorly, inferior to the corpus callosum, before curving toward the hypothalamus. Many fibers of the fornix end in the mammillary bodies of the hypothalamus.

In the diencephalon, several other nuclei in the wall (thalamus) and floor (hypothalamus) are components of the limbic system. The anterior nuclei of thalamus (Figure 14-12b) relay information from the mammillary body (of the hypothalamus) to the cingulate gyrus on that side. The boundaries between the hypothalamic nuclei of the limbic system are often poorly defined, but experimental stimulation has outlined important hypothalamic centers responsible for the emotions of rage, fear, pain, sexual arousal, and pleasure.

The stimulation of specific regions of the hypothalamus can also produce either heightened alertness and excitement or lethargy and sleep. These responses are caused by the stimulation or inhibition of the reticular formation.

14-9 The cerebrum contains motor, sensory, and association areas, allowing for higher mental functions

Learning Outcome Identify the major anatomical subdivisions and functions of the cerebrum and discuss the origin and significance of the major types of brain waves seen in an electroencephalogram (EEG).

The cerebrum is the largest region of the brain. Gray matter in the cerebrum is located in the cerebral cortex and in deeper basal nuclei. The white matter of the cerebrum lies deep to the cerebral cortex and around the basal nuclei. Conscious thoughts and all intellectual functions originate in the cerebral hemispheres. Much of the cerebrum is involved in processing somatic sensory and motor information. In this section we look at the structure and functions of the parts of the cerebrum.

Structure of the Cerebral Cortex and Cerebral Hemispheres

A layer of cerebral cortex ranging from 1 to 4.5 mm thick covers the paired cerebral hemispheres, which dominate the superior and lateral surfaces of the cerebrum. The gyri increase the surface area of the cerebral hemispheres, and thus the number of cortical

neurons they contain. The total surface area of the cerebral hemispheres is nearly equivalent to 2200 cm² (2.5 ft²) of flat surface.

The entire brain has enlarged over the course of human evolution, but the cerebral hemispheres have enlarged at a much faster rate than has the rest of the brain. This enlargement reflects the large numbers of neurons needed for complex analytical and integrative functions. Since the neurons involved are in the superficial layer of cortex, it is there that the expansion has been most pronounced. The simplest solution to house this neuronal increase, other than an enlargement of the entire skull, was for the cortical layer to fold like a crumpled piece of paper into the sulci and gyri.

Landmarks and features on the surface of one cerebral hemisphere are shown in Figure 14-13a,b. (The two cerebral hemispheres are almost completely separated by a deep **longitudinal cerebral fissure**, as shown in Figure 14-14b). Each cerebral hemisphere can be divided into *lobes*, or regions, named after the overlying bones of the skull.

The brain has a unique pattern of sulci and gyri, as individual as a fingerprint, yet the boundaries between lobes are reliable landmarks. On each hemisphere, the **central sulcus**, a deep groove, divides the anterior **frontal lobe** from the more posterior **parietal lobe**. The **precentral gyrus** of the frontal lobe forms the anterior border of the central sulcus, while the **postcentral gyrus** of the parietal lobe forms its posterior border. The horizontal **lateral sulcus** separates the frontal lobe from the **temporal lobe**. The **insula** (IN-sū-luh; *insula*, island), an “island” of cortex, lies medial to the lateral sulcus (Figure 14-13c). The more posterior **parieto-occipital sulcus** separates the parietal lobe from the **occipital lobe** (Figure 14-13d).

The White Matter of the Cerebrum

The interior of the cerebrum consists mostly of white matter. We can classify the axons of white matter as *association*, *commissural*, or *projection fibers* (Figure 14-14).

- **Association fibers** interconnect areas of cerebral cortex within a single cerebral hemisphere. Shorter association fibers are called **arcuate** (AR-kyū-āt) **fibers**, because they curve in an arc to pass from one gyrus to another. Longer association fibers are organized into discrete bundles, or *fasciculi* (fah-SIK-yū-lī). The **longitudinal fasciculi** connect the frontal lobe to the other lobes of the same hemisphere (Figure 14-14a).
- **Commissural** (kom-ih-SŪR-ul; *commissura*, crossing over) **fibers** interconnect and permit communication between the cerebral hemispheres. Bands of commissural fibers linking the hemispheres include the **corpus callosum** and the **anterior commissure** (Figure 14-14b). The corpus callosum alone contains more than 200 million axons, carrying some 4 billion impulses per second!

Figure 14-13 The Brain in Lateral View.

The central sulcus divides which two cerebral lobes?

Figure 14–14 Fibers of the White Matter of the Cerebrum.

- **Projection fibers** link the cerebral cortex to the diencephalon, brainstem, cerebellum, and spinal cord. All projection fibers pass through the diencephalon. There, axons heading to sensory areas of the cerebral cortex pass among the axons descending from motor areas of the cortex. In gross dissection, the ascending fibers and descending fibers look alike. The entire collection of projection fibers is known as the **internal capsule** (Figure 14–14b).

The Basal Nuclei

While the cerebral cortex is consciously directing a complex movement or solving some intellectual puzzle, other centers of the cerebrum, diencephalon, and brainstem are processing sensory information and issuing motor commands outside conscious awareness. Many of these activities, which occur at the subconscious level, are directed by the basal nuclei.

Structure of the Basal Nuclei

The **basal nuclei** are masses of gray matter that lie within each hemisphere deep to the floor of the lateral ventricle

(Figure 14–15a). They are embedded in the white matter of the cerebrum. The radiating projection fibers and commissural fibers travel around or between these nuclei.

Historically, the basal nuclei have been considered part of a larger functional group known as the *basal ganglia*. This group included the basal nuclei of the cerebrum and the associated motor nuclei in the diencephalon and mid-brain. We will consider the functional interactions among these components in Chapter 15, but we will avoid the term “basal ganglia” because ganglia are otherwise restricted to the PNS.

The **caudate** (KOW-dāt) **nucleus** has a large head and a slender, curving tail that follows the curve of the lateral ventricle. The head of the caudate nucleus lies anterior to the **lentiform nucleus**. The lentiform nucleus consists of a lateral **putamen** (pū-TĀ-men; Figure 14–15b) and a medial **globus pallidus** (GLŌ-bus PAL-ih-dus; pale globe). The term *corpus striatum* (striated body) has been used to refer to the caudate and lentiform nuclei, or to the caudate nucleus and putamen. The name refers to the striated (striped) appearance of the internal capsule as its fibers pass among these nuclei.

Figure 14–15 The Basal Nuclei.

Which portion of the lentiform nucleus is more medial and which portion is more lateral?

The **claustrum** is a thin layer of gray matter lying close to the putamen. The amygdaloid body, part of the limbic system, lies anterior to the tail of the caudate nucleus and inferior to the lentiform nucleus (**Figure 14–15c**).

Functions of the Basal Nuclei

The basal nuclei are involved with the subconscious control of skeletal muscle tone and the coordination of learned movement patterns. Under normal conditions, these nuclei do not initiate movements. But once a movement is under way, the basal nuclei provide the general pattern and rhythm, especially for movements of the trunk and proximal limb muscles. For example:

- When a person walks, the basal nuclei control the cycles of arm and thigh movements that occur between the time they decide to “start” walking and the time they give the “stop” order.
- As a person begins a voluntary movement, the basal nuclei control and adjust muscle tone, particularly in the appendicular muscles, to set body position. When a person decides to pick up a pencil, they consciously reach and grasp with their forearm, wrist, and hand, while the basal nuclei operate at the subconscious level to position their shoulder and stabilize their arm.

How do the basal nuclei carry out their functions? They alter the motor commands issued by the cerebral cortex through a feedback loop. Information arrives at the caudate nucleus and putamen from the cerebral cortex. Lateral processing then takes place in these nuclei and in the adjacent globus pallidus. Most of the output of the basal nuclei exits the globus pallidus and synapses in the thalamus. Nuclei in the thalamus then project the information to appropriate areas of the cerebral cortex.

Activity of the basal nuclei is inhibited by the dopamine (a neurotransmitter) released by neurons in the substantia nigra of the midbrain. If the substantia nigra is damaged or the neurons secrete less dopamine, the basal nuclei become more active. The result is a gradual, generalized increase in muscle tone and the appearance of symptoms characteristic of **Parkinson’s disease**. People with Parkinson’s disease have difficulty starting voluntary movements because opposing muscle groups do not relax. Instead, they must be overpowered. Once a movement is under way, every aspect must be voluntarily controlled through intense effort and concentration.

Motor, Sensory, and Association Areas of the Cortex

The cortex of the cerebral hemispheres contains functional areas whose boundaries are less clearly defined than are those of the cerebral lobes. Some of these areas deal with sensory information, called *sensory areas*, and others with

motor commands, called *motor areas*. The central sulcus separates the motor and sensory areas of the cortex. There are also cortical areas called *association areas* that coordinate incoming and outgoing data from the sensory and motor areas. The major motor, sensory, and association areas of the cerebral cortex are shown in **Figure 14–16** and listed in **Table 14–3**.

The cortex of each cerebral hemisphere receives somatosensory information from, and sends motor commands to, the opposite side of the body. For example, the motor areas of the left cerebral hemisphere control muscles on the right side, and the right cerebral hemisphere controls muscles on the left side. This crossing over has no known functional significance.

The correspondence between a specific function and a specific area of the cerebral cortex is imprecise. Because the boundaries are indistinct and have considerable overlap, one area may have several functions. Some aspects of cortical function, such as consciousness, cannot easily be assigned to any single area. However, we know that most individuals use all portions of the brain. Let’s look at these important areas of the cortex in more detail.

Motor Areas

The surface of the precentral gyrus is the **primary motor cortex** (**Figure 14–16a**). Neurons of the primary motor cortex direct voluntary movements by controlling somatic motor neurons in the brainstem and spinal cord. These cortical neurons are called **pyramidal cells** because their cell bodies resemble little pyramids.

The primary motor cortex is like the keyboard of a piano. Striking a specific piano key produces a specific sound. Similarly, stimulating a specific motor neuron in the primary motor cortex generates a contraction in a specific skeletal muscle.

Table 14–3 The Cerebral Cortex

Lobe/Area	Function
FRONTAL LOBE	
Primary motor cortex	Voluntary control of skeletal muscles
PARIETAL LOBE	
Primary somatosensory cortex	Conscious perception of touch, pressure, pain, vibration, taste, and temperature
OCCIPITAL LOBE	
Visual cortex	Conscious perception of visual stimuli
TEMPORAL LOBE	
Auditory cortex and olfactory cortex	Conscious perception of auditory (hearing) and olfactory (smell) stimuli
ALL LOBES	
Motor, sensory, somatosensory, and association areas	Integration and processing of sensory data; processing and initiation of motor activities

Figure 14–16 Motor, Sensory, and Association Areas of the Cerebral Cortex.

Sensory Areas

Like the monitoring gauges in the dashboard of a car, the sensory areas of the cerebral cortex report key information. At each location, sensory information is reported in the pattern of neuron activity in the cortex. The surface of the postcentral gyrus contains the **primary somatosensory cortex**. Neurons in this region receive general somatic sensory information from receptors for touch, pressure, pain, vibration, or temperature. A person is aware of these sensations only when nuclei in the thalamus relay the information to the primary somatosensory cortex.

Sight, sound, smell, and taste sensations arrive at other areas of the cerebral cortex (**Figure 14–16a**). The **visual cortex**

of the occipital lobe receives visual information. The **auditory cortex** and **olfactory cortex** of the temporal lobe receive information about hearing and smell, respectively. The **gustatory cortex**, which receives information from taste receptors of the tongue and pharynx, lies in the anterior portion of the insula and adjacent portions of the frontal lobe.

Association Areas

The sensory and motor regions of the cortex are connected to nearby **association areas**, regions of the cortex that interpret incoming data or coordinate a motor response (**Figure 14–16a**). Like the information provided by the gauges in a car, the arriving data must be noticed and interpreted before the driver

can take appropriate action. *Sensory association areas* are cortical regions that monitor and interpret the information that arrives at the sensory areas of the cortex. Examples include the somatosensory association cortex, visual association area, and premotor cortex.

The **somatosensory association cortex** monitors activity in the primary somatosensory cortex. This association area allows a person to recognize a touch as light as a mosquito landing on their arm (and gives them a chance to swat the mosquito before it bites).

The special senses of smell, sight, and hearing involve separate areas of the sensory cortex, and each has its own association area. These areas monitor and interpret arriving sensations. For example, the **visual association area** monitors the patterns of activity in the visual cortex and interprets the results. A person sees the symbols *c*, *a*, and *r* when the stimulation of receptors in their eyes leads to the stimulation of neurons in their visual cortex. Their visual association area recognizes that these are letters and that $c + a + r = car$. An individual with a damaged visual association area could scan the lines of a printed page and see rows of symbols that are clear but would perceive no meaning from the symbols. Similarly, the **auditory association area** monitors sensory activity in the auditory cortex. Word recognition takes place in this association area.

The **premotor cortex**, or **somatic motor association area**, coordinates learned movements. The primary motor cortex does nothing on its own, any more than a piano keyboard can play itself. The neurons in the primary motor cortex must be stimulated by neurons in other parts of the cerebrum. When a voluntary movement is performed, the premotor cortex relays the instructions to the primary motor cortex. With repetition, the proper pattern of stimulation becomes stored in the premotor cortex. Movements can then be done smoothly and easily by triggering the *pattern* rather than by controlling the individual neurons. This principle applies to any learned movement, from something as simple as picking up a glass to something as complex as playing the piano. One area of the premotor cortex, the *frontal eye field*, controls learned eye movements, such as when one scans these lines of type (**Figure 14–16b**). Individuals with damage to the frontal eye field can understand written letters and words but cannot read, because their eyes cannot follow the lines on a printed page.

Integrative Centers and Higher Mental Functions

Integrative centers receive information from many association areas and direct extremely complex motor activities. They also perform analytical functions. For example, the *prefrontal cortex* of the frontal lobe integrates information from sensory association areas and performs intellectual functions, such

as predicting the consequences of possible responses. These centers are in the lobes and cortical areas of both cerebral hemispheres.

Integrative centers concerned with complex processes, such as mathematical computation, speech, writing, and understanding spatial relationships, are largely restricted to either the left or the right hemisphere. Although the two hemispheres look almost identical, they have different functions, a phenomenon called *hemispheric lateralization*. The corresponding regions on the opposite hemisphere are also active, but their functions are less well defined.

The Specialized Language Areas in the Brain

Language processing is much more complicated than previously thought, and brain imaging studies have shown that language processing occurs in both hemispheres and varies from one person to the next.

Two important cortical areas with varying functions related to human language are *Wernicke's area* and *Broca's area*. Both are primarily associated with the left cerebral hemisphere. **Wernicke's** (VER-nih-kēz) **area** is near the auditory cortex and is associated with language comprehension. This analytical center receives information from the sensory association areas and plays an important role in personality by integrating sensory information and coordinating access to visual and auditory memories.

Broca's area (*motor speech area*) is near the motor cortex and is associated with speech production. Broca's area regulates the patterns of breathing and vocalization needed for normal speech. This regulation involves coordinating the activities of the respiratory muscles, the laryngeal and pharyngeal muscles, and the muscles of the tongue, cheeks, lips, and jaws. A person with damage to Broca's area can make sounds but not words.

The motor commands issued by the motor speech area are adjusted by feedback from the auditory association area, also called the *receptive speech area*. Damage to the related sensory areas can cause a variety of speech-related problems. (See the Clinical Note: Aphasia and Dyslexia.) Some affected individuals have difficulty speaking although they know exactly which words to use. Others talk constantly but use all the wrong words.

The Prefrontal Cortex

The **prefrontal cortex** of the frontal lobe coordinates information relayed from all the cortical association areas (see **Figure 14–16b**). In doing so, it performs such abstract intellectual functions as predicting the consequences of events or actions. The prefrontal cortex does not fully develop until the early 20s. Damage to the prefrontal cortex leads to difficulties in estimating temporal relationships between events. Questions such as "How long ago did this happen?" or "What happened first?" become difficult to answer.

Clinical Note Aphasia and Dyslexia

Speech therapists help children and adults struggling with speaking and swallowing disorders. **Aphasia** (ah-FĀ-zē-ah; a-, without + *phasia*, speech) is a disorder affecting the ability to speak or read. *Global aphasia* results from extensive damage to the specialized language areas of the brain or to the associated sensory tracts. Affected individuals are unable to speak, read, or understand speech. Global aphasia often accompanies a stroke that is severe enough to affect a large area of cortex, including the speech and language areas. Recovery is possible, but the process often takes months or even years.

Dyslexia (dys-, difficult, faulty + *lexis*, diction) is a disorder affecting the comprehension and use of written words. Up to 15% of children in the United States have some degree of dyslexia. Children with dyslexia have difficulty reading and writing, although their other intellectual functions are not affected. Their writing looks uneven and disorganized. They typically write letters in the wrong order (*dig* becomes *gid*) or reverse them (*E* becomes *Ǝ*). Recent evidence suggests that at least some forms of dyslexia result from problems in processing, sorting, and integrating visual or auditory information.

The prefrontal cortex has extensive connections with other cortical areas and with other portions of the brain. Feelings of frustration, tension, and anxiety are generated as the prefrontal cortex interprets ongoing events and makes predictions about future situations or consequences. If the connections between the prefrontal cortex and other brain regions are physically severed, the frustrations, tensions, and anxieties are removed. During the middle of the 20th century, this rather drastic procedure, called **prefrontal lobotomy**, was used to “cure” a variety of mental illnesses, especially those associated with violent or antisocial behavior. After a lobotomy, the patient would no longer be concerned about what had previously been a major problem, whether psychological (hallucinations) or physical (severe pain). However, the individual was often equally unconcerned about tact, decorum, and toilet training. Since then, drugs that target specific pathways and regions of the CNS have been developed, so lobotomies are no longer used to change behavior.

Hemispheric Lateralization

Each of the two cerebral hemispheres is responsible for specific functions that are not ordinarily performed by the opposite hemisphere, a type of specialization known as **hemispheric lateralization**. In most people, the left hemisphere contains the specialized language areas of the brain and is responsible for language-based skills. For example,

reading, writing, and speaking depend on processing done in the left cerebral hemisphere. In addition, the premotor cortex involved with hand movements is larger on the left side for right-handed people than for left-handed people. The left hemisphere is also important in performing analytical tasks, such as mathematical calculations and logical decision making.

The right cerebral hemisphere analyzes sensory information and relates the body to the sensory environment. Interpretive centers in this hemisphere permit identification of familiar objects by touch, smell, sight, or taste. For example, the right hemisphere plays a dominant role in recognizing faces and in understanding three-dimensional relationships. It is also important in analyzing the emotional context of a conversation—for instance, distinguishing between the threat “Get lost!” and the question “Get lost?” Individuals with a damaged right hemisphere may be unable to add emotional inflections to their own words.

Left-handed people represent about 10% of the human population. In most cases, the primary motor cortex of the right hemisphere controls motor function for the dominant (left) hand. However, the centers involved with speech and analytical function are in the left hemisphere, just as they are in right-handed people. Interestingly, an unusually high percentage of musicians and artists are left-handed. Additionally, the more a person favored one hand over the other, the stronger the connection was with the other side of the brain. This suggests that as a species, we became left-handed or right-handed when we started developing language about 100,000 years ago.

Monitoring Brain Activity: The Electroencephalogram (EEG)

Various methods have led to maps of brain activity and brain function. The primary somatosensory cortex and the primary motor cortex have been mapped by direct stimulation in patients undergoing brain surgery. The functions of other regions of the cerebrum can be revealed by the behavioral changes that follow localized injuries or strokes. The activities of specific regions can be visualized by a *PET scan* or through *functional magnetic resonance imaging* (fMRI).

Clinicians commonly monitor the electrical activity of the brain to assess brain activity. Neural function depends on electrical events of the plasma membrane of neurons. The brain contains billions of neurons, and their activity generates an electrical field that can be measured by electrodes placed on the brain or on the outer surface of the skull. The electrical activity changes constantly, as nuclei and cortical areas are stimulated or quiet down. A printed recording of the electrical activity of the brain is called an **electroencephalogram (EEG)**. The electrical patterns observed are called *brain waves*.

Figure 14–17 Brain Waves. The four electrical patterns revealed by electroencephalograms (EEGs). The heights (amplitudes) of the four waves are not drawn to the same scale.

The four types of typical brain waves are shown in **Figure 14–17**. **Alpha waves** occur in the brains of healthy, awake adults who are resting with their eyes closed. Alpha waves disappear during sleep, but they also vanish when the individual begins to concentrate on some specific task. During attention to stimuli or tasks, higher-frequency **beta waves** replace alpha waves. Beta waves are typical of individuals who are concentrating on a task, under stress, or in a state of psychological tension. **Theta waves** may appear transiently during relaxation or sleep but are most often observed in children and in intensely frustrated adults. The presence of theta waves under other circumstances may indicate the presence of a brain disorder, such as a tumor. **Delta waves** are very-large-amplitude, low-frequency waves. They are normally seen during deep sleep in people of all ages. Delta waves are also seen in the brains of infants (whose brains are still developing) and in awake adults when a tumor, vascular blockage, or inflammation has damaged portions of the brain.

Electrical activity in the two hemispheres is generally synchronized by a “pacemaker” mechanism that appears to involve the thalamus. Lack of synchronization between the

hemispheres can indicate localized damage or other cerebral abnormalities. For example, a tumor or injury affecting one hemisphere typically changes the pattern in that hemisphere, and the patterns of the two hemispheres are no longer aligned.

A **seizure** is a temporary cerebral disorder accompanied by uncontrollable movements, unusual sensations, inappropriate behavior, or some combination of these symptoms. Clinical conditions characterized by seizures are known as seizure disorders, or *epilepsies*. The nature of the signs and symptoms produced depends on the region of the cortex involved. If a seizure affects the primary motor cortex, movements will occur. If it affects the auditory cortex, the individual will hear strange sounds. Seizures of all kinds are accompanied by a marked change in the pattern of electrical activity recorded in an electroencephalogram. The change begins in one portion of the cerebral cortex but may then spread across the entire cortical surface, like a wave on the surface of a pond.

We now focus our attention to the cranial nerves. Then we discuss the cranial reflexes that rely on these nerves.

FOCUS

Cranial Nerves

Cranial nerves are PNS components that connect directly to the brain. The 12 pairs of cranial nerves are visible on the ventral surface of the brain (**Figure 14–18**). Each has a name related to its distribution or its function.

The number assigned to a cranial nerve corresponds to the nerve's position along the longitudinal axis of the brain, beginning at the cerebrum. In scientific writing, the abbreviation for cranial nerve, CN, is followed by a Roman numeral. For example, CN II refers to cranial nerve II or the optic nerve. If the full name of the cranial nerve is given, then only the Roman numeral is necessary, such as optic nerve (II).

Each cranial nerve attaches to the brain near the associated sensory or motor nuclei. The sensory nuclei act as switching centers, with the postsynaptic neurons relaying the information

to other nuclei or to processing centers in the cerebral or cerebellar cortex. In a similar way, the motor nuclei receive convergent inputs from higher centers or from other nuclei along the brainstem.

In this section, we classify cranial nerves as primarily sensory, special sensory, motor, or mixed (sensory and motor). In this classification, sensory nerves carry somatic sensory information, including touch, pressure, vibration, temperature, or pain. Special sensory nerves carry the sensations of smell, sight, hearing, or balance. Motor nerves are dominated by the axons of somatic motor neurons. Mixed nerves have a mixture of sensory and motor fibers. This classification scheme is useful, but it is based on the primary function, and a cranial nerve can have important secondary functions. Here are three examples:

Figure 14–18 Origins of the Cranial Nerves. An inferior view of the brain.

- The olfactory receptors, the visual receptors, and the receptors of the internal ear are innervated by cranial nerves that are dedicated almost entirely to carrying special sensory information. In contrast, the sensation of taste, considered to be one of the special senses, is carried by axons that form only a small part of large cranial nerves that have other primary functions.
- As elsewhere in the PNS, a nerve containing tens of thousands of motor fibers that lead to a skeletal muscle also contains sensory fibers from muscle spindles and Golgi tendon organs (proprioceptive sensory nerve endings) in that muscle. We assume that these sensory fibers are present but ignore them in classifying the nerve.
- Regardless of their other functions, several cranial nerves (III, VII, IX, and X) distribute autonomic fibers to peripheral ganglia, just as spinal nerves deliver them to ganglia along the spinal cord. We note the presence of small numbers of autonomic fibers (discussed further in Chapter 16) but ignore them in the classification of the nerve.

Cranial nerves are clinically important, in part because they can provide clues to underlying CNS problems. Clinicians assess cranial nerve function using various standardized tests.

Tips

Two useful mnemonics for remembering the names of the cranial nerves in numerical order are “**Oh Oh Oh, To Touch And Feel Very Green Vegetables, Ah Heaven!**” and “**Oh, Once One Takes The Anatomy Final, Very Good Vacations Are Heavenly!**”

The Olfactory Nerves (I)

- **Primary function:** Special sensory (smell)
- **Origin:** Receptors of olfactory epithelium
- **Pass through:** Olfactory foramina in cribriform plate of ethmoid
- **Destination:** Olfactory bulbs

The first pair of cranial nerves carries special sensory information responsible for the sense of smell (**Figure 14–19**). The olfactory receptors are specialized neurons in the epithelium covering the roof of the nasal cavity, the superior nasal

Figure 14–19 The Olfactory Nerve.

conchae, and the superior parts of the nasal septum. Axons from these sensory neurons collect to form 20 or more bundles that penetrate the cribriform plate of the ethmoid. These bundles are components of the **olfactory nerves (I)**. These bundles enter the **olfactory bulbs**, neural masses on either side of the crista galli. The olfactory afferents synapse within the olfactory bulbs. The axons of the postsynaptic neurons proceed to the cerebrum along the slender **olfactory tracts (Figures 14–19, 14–20)**.

Because the olfactory tracts look like typical peripheral nerves, anatomists about a century ago misidentified these tracts as the first cranial nerve. Later studies demonstrated that the olfactory tracts and bulbs are part of the cerebrum, but by then the numbering system was already firmly established. Anatomists were left with a forest of tiny olfactory nerve bundles lumped together as cranial nerve I.

The olfactory nerves are the only cranial nerves attached directly to the cerebrum. The rest originate or terminate within nuclei of the diencephalon or brainstem, and the ascending sensory information synapses in the thalamus before reaching the cerebrum.

Figure 14–20 The Optic Nerve.

Which structure receives visual information before it reaches the visual cortex?

The Optic Nerves (II)

- **Primary function:** Special sensory (vision)
- **Origin:** Retina of eye
- **Pass through:** Optic canals of sphenoid
- **Destination:** Diencephalon by way of the optic chiasm

The **optic nerves (II)** carry visual information from special sensory ganglia in the eyes (**Figure 14–20**). These nerves contain about 1 million sensory nerve fibers. The optic nerves pass through the optic canals of the sphenoid. Then they converge at the ventral, anterior margin of the diencephalon, at the

optic chiasm (*chiasma*, a crossing). At the optic chiasm, fibers from the medial half of each retina cross over to the opposite side of the brain.

The reorganized axons continue toward the lateral geniculate body of the thalamus as the **optic tracts** (**Figures 14–19, 14–21**). After synapsing in the lateral geniculate body, projection fibers deliver the information to the visual cortex of the occipital lobes. With this arrangement, each cerebral hemisphere receives visual information from the lateral half of the retina of the eye on that side and from the medial half of the retina of the eye of the opposite side. A few axons in the optic tracts bypass the lateral geniculate body and synapse in the superior colliculi of the midbrain. That pathway is discussed in Chapter 17, The Special Senses.

The Oculomotor Nerves (III)

- **Primary function:** Motor (eye movements)
- **Origin:** Midbrain
- **Pass through:** Superior orbital fissures of sphenoid
- **Destination:** *Somatic motor:* superior, inferior, and medial rectus muscles; inferior oblique; levator palpebrae superioris. *Visceral motor:* intrinsic eye muscles

The midbrain contains the motor nuclei controlling the third and fourth cranial nerves. Each **oculomotor nerve (III)** innervates four of the six extrinsic muscles that move the eye and the levator palpebrae superioris, which raises the upper eyelid (**Figure 14–21**). On each side of the brain, CN III emerges from the ventral surface of the midbrain and penetrates the posterior wall of the orbit at the superior orbital fissure. Individuals with damage to this nerve often complain of pain over the eye, droopy eyelids, and double vision, because the movements of the left and right eyes cannot be coordinated properly.

The oculomotor nerve also delivers preganglionic autonomic fibers to neurons of the **ciliary ganglion**. These neurons control intrinsic eye muscles. These muscles change the diameter of the pupil, adjusting the amount of light entering the eye. They also change the shape of the lens to focus images on the retina.

Figure 14–21 Cranial Nerves Controlling the Extrinsic Eye Muscles.

The Trochlear Nerves (IV)

- **Primary function:** Motor (eye movements)
- **Origin:** Midbrain
- **Pass through:** Superior orbital fissures of sphenoid
- **Destination:** Superior oblique

A **trochlear** (TRŌK-lē-ar; *trochlea*, a pulley) **nerve (IV)**, the smallest cranial nerve, innervates the superior oblique of each eye (**Figure 14–21**). The trochlea is a pulley-shaped, ligamentous sling. Each superior oblique passes through a trochlea on its way to its insertion on the surface of the eye. An individual with damage to cranial nerve IV or to its nucleus has difficulty looking down and to the side.

The Abducens Nerves (VI)

- **Primary function:** Motor (eye movements)
- **Origin:** Pons
- **Pass through:** Superior orbital fissures of sphenoid
- **Destination:** Lateral rectus

The **abducens** (ab-DŪ-senz) **nerve (VI)** innervates the lateral rectus, the sixth pair of extrinsic eye muscles (**Figure 14–21**). Contraction of the lateral rectus makes the eye look to the side. In essence, the *abducens* causes *abduction* of the eye. Each abducens nerve emerges from the inferior surface of the brainstem at the border between the pons and the medulla oblongata (**Figure 14–22**). Along with the oculomotor and trochlear nerves from that side, it reaches the orbit through the superior orbital fissure.

Figure 14–22 The Trigeminal Nerve.

What are the three divisions of the trigeminal nerve?

The Trigeminal Nerves (V)

- **Primary function:** Mixed (sensory and motor) to face
- **Origin:** *Ophthalmic nerve* (V₁) (sensory): orbital structures, cornea, nasal cavity, skin of forehead, upper eyelid, eyebrow, nose (part). *Maxillary nerve* (V₂) (sensory): lower eyelid, upper lip, gums, and teeth; cheek; nose, palate, and pharynx (part). *Mandibular nerve* (V₃) (mixed): sensory from lower gums, teeth, and lips; palate and tongue (part); motor from motor nuclei of pons
- **Pass through (on each side):** Ophthalmic nerve through superior orbital fissure, maxillary nerve through foramen rotundum, mandibular nerve through foramen ovale
- **Destination:** Ophthalmic, maxillary, and mandibular nerves to sensory nuclei in pons; mandibular nerve also innervates muscles of mastication

The pons contains nuclei associated with three cranial nerves (V, VI, and VII) and contributes to a fourth (VIII). The **trigeminal** (trĭ-JEM-i-nal) **nerves (V)**, the largest cranial nerves, are mixed nerves. Each provides both somatic sensory information from the head and face and motor control over muscles of mastication. Sensory (posterior) and motor (anterior) roots originate on the lateral surface of the pons (**Figure 14–22**). The sensory branch is larger, and the enormous **semilunar ganglion** contains the cell bodies of the sensory neurons.

As the name implies, the trigeminal has three major divisions. The small motor root contributes to only one of the three. **Tic douloureux** (dū-luh-ROO; *douloureux*, painful), or *trigeminal neuralgia*, is a painful condition affecting the area innervated by the maxillary and mandibular divisions of the trigeminal nerve. People with the condition often report debilitating pain triggered by contact with the lips, tongue, or gums. The cause of the condition is unknown.

The trigeminal nerve divisions are associated with the *ciliary*, *sphenopalatine*, *submandibular*, and *otic ganglia*. These are autonomic (parasympathetic) ganglia whose neurons innervate structures of the face. Although its nerve fibers may pass around or through these ganglia, the trigeminal nerve does not contain visceral motor fibers. We discussed the ciliary ganglion in the previous Oculomotor Nerves (III) section and describe the other ganglia next, with the branches of the *facial nerves* (VII) and the *glossopharyngeal nerves* (IX).

Tips

To learn the sensory distribution of the trigeminal nerve, place the first three fingers across the face with the index finger just below the eye (ophthalmic), the middle finger on the upper lip (maxillary), and the third finger (mandibular) on the chin.

The Facial Nerves (VII)

- **Primary function:** Mixed (sensory and motor) to face
- **Origin:** *Sensory:* taste receptors on anterior two-thirds of tongue. *Motor:* motor nuclei of pons
- **Pass through:** Internal acoustic meatus to canals leading to the stylomastoid foramina

- **Destination:** *Sensory:* sensory nuclei of pons. *Somatic motor:* muscles of facial expression. *Visceral motor:* lacrimal (tear) gland and nasal mucous glands by way of the pterygopalatine ganglion; submandibular and sublingual glands by way of the submandibular ganglion

The **facial nerves (VII)** are mixed nerves. The cell bodies of the sensory neurons are found in the **geniculate ganglia**, and the motor nuclei are in the pons. On each side, the sensory and motor roots emerge from the pons and enter the internal acoustic meatus of the temporal bone. Each facial nerve then passes through the facial canal to reach the face by way of the stylomastoid foramen. The nerve then splits to form the temporal, zygomatic, buccal, marginal mandibular, and cervical branches (**Figure 14–23**).

The sensory neurons monitor proprioceptors in the facial muscles and provide deep pressure sensations over the face. They also receive taste information from receptors along the anterior two-thirds of the tongue. Somatic motor fibers control the superficial muscles of the scalp and face and deep muscles near the ear.

The facial nerves carry preganglionic autonomic fibers to the pterygopalatine and submandibular ganglia. Postganglionic

Figure 14–23 The Facial Nerve.

fibers from the **pterygopalatine ganglia** innervate the lacrimal glands and small glands of the nasal cavity and pharynx. The **submandibular ganglia** innervate the *submandibular* and *sublingual* (*sub-*, under + *lingual*, pertaining to the tongue) glands.

Bell's palsy is a cranial nerve disorder that results from an inflammation of a facial nerve. The condition is probably due to a viral infection. Signs and symptoms include paralysis of facial muscles on the affected side and loss of taste sensations from the anterior two-thirds of the tongue. The condition is usually painless. In most cases the symptoms fade after a few weeks or months.

The Vestibulocochlear Nerves (VIII)

- **Primary function:** Special sensory: balance and equilibrium (vestibular nerve) and hearing (cochlear nerve)
- **Origin:** Monitor receptors of the internal ear (vestibule and cochlea)
- **Pass through:** Internal acoustic meatus of temporal bones
- **Destination:** Vestibular and cochlear nuclei of pons and medulla oblongata

The **vestibulocochlear nerves (VIII)** are also known as the *acoustic nerves*, the *auditory nerves*, and the *stato-acoustic nerves*.

We use *vestibulocochlear* because this term indicates the names of its two major nerve branches: the *vestibular nerve* and the *cochlear nerve*. Each vestibulocochlear nerve lies posterior to the origin of the facial nerve, straddling the boundary between the pons and the medulla oblongata (**Figure 14–24**). This nerve reaches the sensory receptors of the internal ear by entering the internal acoustic meatus in company with the facial nerve.

Each vestibulocochlear nerve has two distinct bundles of sensory fibers. The **vestibular** (*vestibulum*, cavity) **nerve** originates at the receptors of the *vestibule*, the portion of the internal ear concerned with balance sensations. The sensory neurons are in an adjacent sensory ganglion, and their axons target the **vestibular nuclei** of the pons and medulla oblongata. These afferents convey information about the orientation and movement of the head. The **cochlear** (*cochlea*, snail shell) **nerve** monitors the receptors in the *cochlea*, the portion of the internal ear that provides the sense of hearing. The cell bodies of the sensory neurons are located within a peripheral ganglion (the *spiral ganglion*), and their axons synapse within the **cochlear nuclei** of the pons and medulla oblongata. Axons leaving the vestibular and cochlear nuclei relay the sensory information to other centers or initiate reflexive motor responses. Balance and the sense of hearing are discussed in Chapter 17, The Special Senses.

Figure 14–24 The Vestibulocochlear Nerve.

The Glossopharyngeal Nerves (IX)

- **Primary function:** Mixed (sensory and motor) to head and neck
- **Origin:** *Sensory:* posterior one-third of the tongue, part of the pharynx and palate, carotid arteries of the neck. *Motor:* motor nuclei of medulla oblongata
- **Pass through:** Jugular foramina between the occipital bone and the temporal bones
- **Destination:** *Sensory:* sensory nuclei of medulla oblongata. *Somatic motor:* pharyngeal muscles involved in swallowing. *Visceral motor:* parotid gland by way of the otic ganglion

The medulla oblongata contains the sensory and motor nuclei of cranial nerves IX, X, XI, and XII, in addition to the vestibular nucleus of nerve VIII. The **glossopharyngeal** (glos-ō-fah-RIN-jē-al; *glossum*, tongue) **nerves (IX)** innervate the tongue and

pharynx. Each glossopharyngeal nerve penetrates the cranium within the jugular foramen, with cranial nerves X and XI.

The glossopharyngeal nerves are mixed nerves, but sensory fibers are most abundant. The sensory neurons on each side are in the **superior (jugular) ganglion** and **inferior (petrosal) ganglion** (**Figure 14–25**). The sensory fibers carry general sensory information from the lining of the pharynx and the soft palate to a nucleus in the medulla oblongata. These nerves also provide taste sensations from the posterior third of the tongue. Additionally, they have special receptors that monitor the blood pressure and dissolved gas concentrations in the carotid arteries, major blood vessels in the neck.

The somatic motor fibers control the pharyngeal muscles involved in swallowing. Visceral motor fibers synapse in the **otic ganglion**. Postganglionic fibers innervate the parotid gland of the cheek.

Figure 14–25 The Glossopharyngeal Nerve.

The Vagus Nerves (X)

- **Primary function:** Mixed (sensory and motor), widely distributed in the thorax and abdomen
- **Origin:** *Sensory:* pharynx (part), auricle and external acoustic meatus (a portion of the external ear), diaphragm, and visceral organs in thoracic and abdominopelvic cavities. *Motor:* motor nuclei in medulla oblongata

Figure 14-26 The Vagus Nerve.

- **Pass through:** Jugular foramina between the occipital bone and the temporal bones
- **Destination:** *Sensory:* sensory nuclei and autonomic centers of medulla oblongata. *Visceral motor:* muscles of the palate, pharynx, digestive, respiratory, and cardiovascular systems in the thoracic and abdominal cavities

The **vagus** (VĀ-gus) **nerves** (X) arise immediately posterior to the attachment of the glossopharyngeal nerves. Many small rootlets contribute to their formation. Developmental studies indicate that these nerves probably represent the fusion of several smaller cranial nerves during our evolutionary history. *Vagus* means wandering, and the vagus nerves branch and radiate extensively. **Figure 14-26** shows only the general pattern of distribution.

Sensory neurons are in the **superior** (*jugular*) **ganglion** and the **inferior** (*nodose*; NŌ-dōs) **ganglion**. Each vagus nerve provides somatic sensory information about the external acoustic meatus and the diaphragm, and special sensory information from pharyngeal taste receptors. But most of the vagal afferents carry visceral sensory information from receptors along the esophagus, respiratory tract, and abdominal viscera as distant as the last portions of the large intestine. This visceral sensory information is vital to the autonomic control of visceral function.

The motor components of the vagus are equally diverse. Each vagus nerve carries preganglionic autonomic (parasympathetic) fibers that affect the heart and control smooth muscles and glands within the areas monitored by its sensory fibers, including the stomach, intestines, and gallbladder. Difficulty in swallowing is one of the most common signs of damage to either cranial nerve IX or X. Damage to either one prevents the coordination of the swallowing reflex.

The Accessory Nerves (XI)

- **Primary function:** Motor to muscles of the neck and upper back
- **Origin:** Motor nuclei of spinal cord and medulla oblongata
- **Pass through:** Jugular foramina between the occipital bone and the temporal bones
- **Destination:** Internal branch innervates voluntary muscles of palate, pharynx, and larynx; external branch controls sternocleidomastoid and trapezius

The **accessory nerves (XI)** are also known as the *spinal accessory nerves* or the *spino-accessory nerves*. Unlike other cranial nerves, each accessory nerve has some motor fibers that originate in the lateral part of the anterior gray horns of the first five cervical segments of the spinal cord (**Figure 14-27**). These somatic motor fibers form the **spinal root** of nerve XI. They enter the cranium through the foramen magnum. They then join the motor fibers of the **cranial root**, which originates at a nucleus in the medulla oblongata. The composite nerve leaves the cranium through the jugular foramen and divides into two branches.

The **internal branch** of nerve XI joins the vagus nerve and innervates the voluntary swallowing muscles of the soft palate and pharynx and the intrinsic muscles that control the vocal cords. The **external branch** of nerve XI controls the sternocleidomastoid and trapezius of the neck and back. The motor fibers of this branch originate in the lateral gray part of the anterior horns of cervical spinal nerves C₁ to C₅.

Figure 14-27 The Accessory and Hypoglossal Nerves.

The Hypoglossal Nerves (XII)

- **Primary function:** Motor (tongue movements)
- **Origin:** Motor nuclei of medulla oblongata
- **Pass through:** Hypoglossal canals of occipital bone
- **Destination:** Muscles of the tongue

Each **hypoglossal** (hī-pō-GLOS-ul) **nerve (XII)** leaves the cranium through the hypoglossal canal. The nerve then curves

to reach the skeletal muscles of the tongue (**Figure 14–27**). This cranial nerve provides voluntary motor control over movements of the tongue. Its condition is checked by having a person stick out their tongue. Damage to one hypoglossal nerve or to its associated nuclei causes the tongue to veer toward the affected side.

Table 14–4 summarizes the basic distribution and function of each cranial nerve.

Table 14–4 Cranial Nerve Branches and Functions

Cranial Nerve (Number)	Sensory Ganglion	Branch	Primary Function	Foramen	Innervation
Olfactory (I)			Special sensory	Olfactory foramina of ethmoid	Olfactory epithelium
Optic (II)			Special sensory	Optic canal	Retina of eye
Oculomotor (III)			Motor	Superior orbital fissure	Superior, inferior, and medial rectus muscles; inferior oblique; levator palpebrae superioris; intrinsic eye muscles
Trochlear (IV)			Motor	Superior orbital fissure	Superior oblique
Trigeminal (V)	Semilunar		Mixed	Superior orbital fissure	Areas associated with the jaws
		Ophthalmic nerve (V ₁)	Sensory	Superior orbital fissure	Orbital structures, nasal cavity, skin of forehead, upper eyelid, eyebrows, nose (part)
		Maxillary nerve (V ₂)	Sensory	Foramen rotundum	Lower eyelid; superior lip, gums, and teeth; cheek, nose (part), palate, and pharynx (part)
		Mandibular nerve (V ₃)	Mixed	Foramen ovale	<i>Sensory:</i> inferior gums, teeth, lips, palate (part), and tongue (part) <i>Motor:</i> muscles of mastication
Abducens (VI)			Motor	Superior orbital fissure	Lateral rectus
Facial (VII)	Geniculate		Mixed	Internal acoustic meatus to facial canal; exits at stylomastoid foramen	<i>Sensory:</i> taste receptors on anterior 2/3 of tongue <i>Motor:</i> muscles of facial expression, lacrimal gland, submandibular gland, sublingual glands
Vestibulocochlear (VIII)		Cochlear nerve Vestibular nerve	Special sensory	Internal acoustic meatus	Cochlea (receptors for hearing) Vestibule (receptors for motion and balance)
Glossopharyngeal (IX)	Superior (jugular) and inferior (petrosal)		Mixed	Jugular foramen	<i>Sensory:</i> posterior 1/3 of tongue; pharynx and palate (part); receptors for blood pressure, pH, oxygen, and carbon dioxide concentrations <i>Motor:</i> pharyngeal muscles and parotid gland
Vagus (X)	Superior (jugular) and inferior (nodose)		Mixed	Jugular foramen	<i>Sensory:</i> pharynx; auricle and external acoustic meatus; diaphragm; visceral organs in thoracic and abdominopelvic cavities <i>Motor:</i> palatal and pharyngeal muscles and visceral organs in thoracic and abdominopelvic cavities
Accessory (XI)		Internal	Motor	Jugular foramen	Skeletal muscles of palate, pharynx, and larynx (with vagus nerve)
		External	Motor	Jugular foramen	Sternocleidomastoid and trapezius
Hypoglossal (XII)			Motor	Hypoglossal canal	Tongue musculature

14

14-10 Cranial reflexes are rapid, automatic responses involving sensory and motor fibers of cranial nerves

Learning Outcome Describe representative examples of cranial reflexes that produce somatic responses or visceral responses to specific stimuli.

Cranial reflexes are automatic responses to stimuli that involve the sensory and motor fibers of cranial nerves. They include both monosynaptic and polysynaptic reflex arcs. Later chapters contain numerous examples of cranial reflexes.

In this section we simply provide an overview and general introduction.

Table 14-5 lists representative examples of cranial reflexes and their functions. There are two main types of cranial reflexes, somatic and visceral. These reflexes are clinically important because they provide a quick and easy method for observing the condition of cranial nerves and specific nuclei and tracts in the brain. The somatic reflexes mediated by the cranial nerves are seldom more complex than the somatic reflexes of the spinal cord that we discussed in Chapter 13. These cranial reflexes are often used to check for damage to the cranial nerves or the associated processing centers in the brain.

The brainstem contains many reflex centers that control visceral motor activity. The motor output of these visceral reflexes is distributed by the autonomic nervous system. As you will see in Chapter 16, the cranial nerves carry most of the commands issued by the parasympathetic division of the ANS. Spinal nerves T₁–L₂ carry the sympathetic commands. Many of the centers that coordinate autonomic reflexes are in the medulla oblongata. These centers can direct very complex visceral motor responses that are essential to the control of respiratory, digestive, and cardiovascular functions.

28. Which reflex and reflex type are tested by shining a light in a person's eye?

See the blue Answers tab at the back of the book.

+ Clinical Note Concussion and Beyond

Contact sports can threaten an athlete's brain—think of boxers taking multiple punches to the head, or soccer players heading the ball. The soft tissue of the brain accelerates and decelerates inside the hard bony box of the cranium.

A *concussion* is the most common type of traumatic brain injury that disturbs brain function. Effects, such as headaches and light sensitivity, are usually temporary. An acutely concussed brain often manifests with headaches that worsen, confusion, and slurred speech. However, the key factor in chronic brain injury is repetition. Football players have left the sport through retirement or injury only to experience progressive signs of diminished concentration, mood disorders (especially depression), personality changes (anger and aggression), cognitive decline (*cognition*, the ability to think), and memory

loss. This phenomenon was first identified in the 1920s by the expression “punch drunk.” The contemporary term is *chronic traumatic encephalopathy*, or *CTE*.

No specific biomarkers (cellular indicators) have yet been identified for CTE. On autopsy, the cerebral hemispheres show diffuse atrophy (loss of mass) and enlarged ventricles. Both neurons and astrocytes appear abnormal. As a result, axonal transmission is impaired.

Why do some athletes develop CTE and others do not? Risk factors remain to be specified, such as the severity and frequency of injury. Prevention strategies include wearing protective headgear. If an athlete sustains a concussion, it is crucial to observe strict “return to play” guidelines. The brain is especially vulnerable to a second injury if the rest period is curtailed.

Table 14–5 Cranial Reflexes

Reflex	Stimulus	Afferents	Central Synapse	Efferents	Response
SOMATIC REFLEXES					
Corneal reflex	Contact with corneal surface	Trigeminal (V)	Motor nucleus for facial (VII)	Facial (VII)	Blinking of eyelids
Tympanic reflex	Loud noise	Vestibulocochlear (VIII)	Inferior colliculus	Facial (VII)	Reduced movement of auditory ossicles
Auditory reflexes	Loud noise	Vestibulocochlear (VIII)	Motor nuclei of brainstem and spinal cord	CN III, IV, VI, VII, X, and cervical nerves	Eye and/or head movements triggered by sudden sounds
Vestibulo-ocular reflexes	Rotation of head	Vestibulocochlear (VIII)	Motor nuclei controlling eye muscles	CN III, IV, VI	Opposite movement of eyes to stabilize field of vision
VISCERAL REFLEXES					
Pupillary reflex	Light striking photoreceptors in one eye	Optic (II)	Superior colliculus	Oculomotor (III)	Pupil constricts
Consensual light reflex	Light striking photoreceptors in one eye	Optic (II)	Superior colliculus	Oculomotor (III)	Pupil constricts in both eyes

14 Chapter Review

Study Outline

An Introduction to the Brain and Cranial Nerves

- The adult human brain contains almost 97% of the body's nervous tissue and averages 1.4 kg (3 lb) in weight and 1200 mL (71 in.³) in volume.

14-1 The brain develops four major regions: the cerebrum, cerebellum, diencephalon, and brainstem

- The four main regions in the adult brain are the **cerebrum**, **cerebellum**, **diencephalon**, and **brainstem**. The brainstem is made up of the **midbrain** (mesencephalon), **pons**, and **medulla oblongata**. (Figure 14–1)
- The brain contains extensive areas of **cortex**, a layer of gray matter on the surfaces of the cerebrum (**cerebral cortex**) and cerebellum.
- The brain forms from three swellings at the superior tip of the developing *neural tube*: the *prosencephalon*, the *mesencephalon*, and the *rhombencephalon*. The prosencephalon ("forebrain") forms the **telencephalon** (which becomes the cerebrum) and diencephalon; the mesencephalon becomes the midbrain; the rhombencephalon ("hindbrain") forms the **metencephalon** (cerebellum and pons) and **myelencephalon** (medulla oblongata). (Table 14–1)
- During development, the central passageway of the brain expands to form chambers called **ventricles**, which contain cerebrospinal fluid (CSF). (Figure 14–2)

14-2 The brain is protected and supported by the cranial meninges, cerebrospinal fluid, and the blood brain-barrier

- The cranial meninges (the *dura mater*, *arachnoid mater*, and *pia mater*) are continuous with the meninges of the spinal cord.

Media Resources:

- Chapter Quizzes, Chapter Practice Test, MP3 Tutor Sessions, and Clinical Case Studies
- Practice Anatomy Lab
- Interactive Physiology
- A&P Flix
- PhysioEx

- Folds of dura mater, including the **falx cerebri**, **tentorium cerebelli**, and **falx cerebelli**, stabilize the position of the brain. (Figure 14–3)
- Cerebrospinal fluid (CSF) (1) protects delicate neural structures, (2) supports the brain, and (3) transports nutrients, chemical messengers, and waste products.
- Cerebrospinal fluid is produced at the **choroid plexuses**, reaches the subarachnoid space through the **lateral** and **median aperture**, and diffuses across the **arachnoid granulations** into the **superior sagittal sinus**. (Spotlight Figure 14–4)
- The **blood-brain barrier (BBB)** isolates nervous tissue from the general circulation.
- The blood-brain barrier is incomplete in parts of the **hypothalamus**, the **pituitary gland**, the **pineal gland**, and the **choroid plexus**.

14-3 Brainstem: The medulla oblongata relays signals between the rest of the brain and the spinal cord

- The medulla oblongata connects the brain and spinal cord. It contains relay stations such as the **olivary nuclei** and **reflex centers**, including the **cardiovascular** and **respiratory**

rhythmicity centers. The **reticular formation** begins in the medulla oblongata and extends into more superior portions of the brainstem. (Figures 14–5, 14–6)

14-4 Brainstem: The pons contains nuclei that process and tracts that relay sensory and motor information

13. The pons contains (1) sensory and motor nuclei for four cranial nerves; (2) nuclei that help control respiration; (3) nuclei and tracts linking the cerebellum with the brainstem, cerebrum, and spinal cord; and (4) ascending, descending, and transverse tracts. (Figure 14–7)

14-5 Brainstem: The midbrain regulates visual and auditory reflexes and controls alertness

14. The **tectum** (roof of the midbrain) contains the **corpora quadrigemina** (**superior colliculi** and **inferior colliculi**). The tegmentum contains the **red nucleus**, the **substantia nigra**, the **cerebral peduncles**, and the headquarters of the reticular activating system (RAS). (Figure 14–8)

14-6 The cerebellum coordinates reflexive and learned patterns of muscular activity at the subconscious level

15. The cerebellum adjusts postural muscles and programs and tunes ongoing movements. The two **cerebellar hemispheres** consist of the **anterior** and **posterior lobes**, the **vermis**, and the **flocculonodular lobe**. (Figure 14–9)
16. The **superior**, **middle**, and **inferior cerebellar peduncles** link the cerebellum with the brainstem, diencephalon, cerebrum, and spinal cord and interconnect the two cerebellar hemispheres.

14-7 The diencephalon integrates sensory information with motor output at the subconscious level

17. The diencephalon is composed of the epithalamus, the thalamus, and the hypothalamus. (Figures 14–10, 14–11)
18. The thalamus is the final relay point for ascending sensory information and coordinates the activities of the basal nuclei and cerebral cortex. (Figures 14–10, 14–11; Table 14–2)
19. The hypothalamus can (1) secrete certain hormones, (2) regulate body temperature, (3) control autonomic function, (4) coordinate voluntary and autonomic functions, (5) coordinate activities of the nervous and endocrine systems, (6) regulate circadian cycles of activity, (7) control skeletal muscle contractions at the subconscious level, and (8) produce emotions and behavioral drives. (Figure 14–11)

14-8 The limbic system is a group of nuclei and tracts that functions in emotion, motivation, and memory

20. The **limbic system**, or *motivational system*, includes the **amygdaloid body**, **cingulate gyrus**, **dentate gyrus**, **parahippocampal gyrus**, **hippocampus**, and **fornix**. The functions of the limbic system involve emotional states, behavioral drives, and memory. (Figure 14–12)

14-9 The cerebrum contains motor, sensory, and association areas, allowing for higher mental functions

21. The cortical surface contains **gyri** (elevated ridges) separated by **sulci** (shallow depressions) or **fissures** (deeper grooves). The **longitudinal cerebral fissure** separates the two **cerebral hemispheres**. The **central sulcus** separates the **frontal** and **parietal lobes**. Other sulci form the boundaries of the **temporal** and **occipital lobes**. (Figure 14–13)
22. The white matter of the cerebrum contains **association fibers**, **commissural fibers**, and **projection fibers**. (Figure 14–14)
23. The **basal nuclei** include the **caudate nucleus**, **globus pallidus**, and **putamen**; they control muscle tone and coordinate learned movement patterns and other somatic motor activities. (Figure 14–15)
24. The **primary motor cortex** of the **precentral gyrus** directs voluntary movements. The **primary somatosensory cortex** of the **postcentral gyrus** receives somatic sensory information from touch, pressure, pain, vibration, taste, and temperature receptors. (Figure 14–16; Table 14–3)
25. **Association areas**, such as the **somatic sensory association area**, **visual association area**, and **premotor cortex** (**somatic motor association area**), control our ability to understand sensory information and coordinate a motor response. (Figure 14–16)
26. The **specialized language areas of the brain** receive information from all the sensory association areas. It is usually dominant in only one hemisphere—generally the left. (Figures 14–16b)
27. The **prefrontal cortex** coordinates information from the secondary and special association areas of the entire cortex and performs abstract intellectual functions. (Figure 14–16)
28. The left hemisphere typically contains the **Broca's area** and **Wernicke's area** and is responsible for language-based skills. The right hemisphere is typically responsible for spatial relationships and analyses.
29. Brain activity is measured with an **electroencephalogram (EEG)**. **Alpha waves** appear in healthy resting adults; **beta waves** occur when adults are concentrating; **theta waves** appear in children; and **delta waves** are normal during sleep. (Figure 14–17)

Focus: Cranial Nerves

30. There are 12 pairs of cranial nerves. Except for CN I and CN II, each nerve attaches to the ventrolateral surface of the brainstem near the associated sensory or motor nuclei. (Figure 14–18)
31. The **olfactory nerves (I)** carry sensory information responsible for the sense of smell. The olfactory afferents synapse within the **olfactory bulbs**. (Figures 14–18, 14–19)
32. The **optic nerves (II)** carry visual information from special sensory receptors in the eyes. (Figures 14–18, 14–20)
33. The **oculomotor nerves (III)** are the primary source of innervation for four of the extrinsic eye muscles. (Figure 14–21)
34. The **trochlear nerves (IV)**, the smallest cranial nerves, innervate the superior oblique muscles of the eyes. (Figure 14–21)
35. The **trigeminal nerves (V)**, the largest cranial nerves, are mixed nerves with three divisions: the **ophthalmic nerve**, **maxillary nerve**, and **mandibular nerve**. (Figure 14–22)

36. The **abducens nerves (VI)** innervate the lateral rectus muscles of the eyes. (Figure 14–21)
 37. The **facial nerves (VII)** are mixed nerves that control muscles of the scalp and face. They provide pressure sensations over the face and receive taste information from the tongue. (Figure 14–23)
 38. The **vestibulocochlear nerves (VIII)** contain the **vestibular nerve**, which monitors sensations of balance, position, and movement, and the **cochlear nerve**, which monitors hearing receptors. (Figure 14–24)
 39. The **glossopharyngeal nerves (IX)** are mixed nerves that innervate the tongue and pharynx and control the action of swallowing. (Figure 14–25)
 40. The **vagus nerves (X)** are mixed nerves that are vital to the autonomic control of visceral function in the thorax and abdomen. (Figure 14–26)
 41. The **accessory nerves (XI)** have **internal branches**, which innervate voluntary swallowing muscles of the soft palate and pharynx, and **external branches**, which control muscles associated with the pectoral girdle. (Figure 14–27)
 42. The **hypoglossal nerves (XII)** provide voluntary motor control over tongue movements. (Figure 14–27)
 43. The branches and functions of the cranial nerves are summarized in Table 14–4.
- 14-10 Cranial reflexes are rapid, automatic responses involving sensory and motor fibers of cranial nerves**
44. **Cranial reflexes** are monosynaptic and polysynaptic reflex arcs that involve sensory and motor fibers of cranial nerves. (Table 14–5)

Review Questions

See the blue Answers tab at the back of the book.

LEVEL 1 Reviewing Facts and Terms

1. Identify the major regions of the brain in the following diagram.

- | | |
|-----------|-----------|
| (a) _____ | (b) _____ |
| (c) _____ | (d) _____ |
| (e) _____ | (f) _____ |

2. Identify the layers of the cranial meninges in the following diagram.

- | | |
|-----------|-----------|
| (a) _____ | (b) _____ |
| (c) _____ | (d) _____ |
| (e) _____ | (f) _____ |
| (g) _____ | |

3. Higher brain centers refer to those areas of the brain involved in higher-order functions. These centers would probably include nuclei, centers, and cortical areas of (a) the cerebrum, (b) the cerebellum, (c) the diencephalon, (d) all of these, (e) a and c only.
4. Cerebrospinal fluid is absorbed into the venous circulation at the (a) arachnoid granulations, (b) roof of the third ventricle, (c) roof of the fourth ventricle, (d) ependymal cells, (e) interventricular foramina.
5. The midbrain contains (a) sensory and motor nuclei of cranial nerve V, (b) the substantia nigra, (c) the arbor vitae, (d) the pineal gland, (e) both a and c.
6. Which brain ventricle does the cerebral aqueduct connect? (a) lateral ventricles, (b) lateral ventricles and the third ventricle, (c) third and fourth ventricles, (d) the fourth ventricle and central canal of the spinal cord.
7. A part of the reticular formation is located in the (a) spine, (b) cerebellum, (c) medulla oblongata, (d) corpus callosum.
8. The primary purpose of the blood-brain barrier (BBB) is to (a) provide the brain with oxygenated blood, (b) drain venous blood by the internal jugular veins, (c) isolate neural tissue in the CNS from the general circulation, (d) do all of these.
9. The centers in the pons that modify the activity of the respiratory rhythmicity centers in the medulla oblongata are the (a) apneustic and pneumotaxic centers, (b) inferior and superior peduncles, (c) cardiac and vasomotor centers, (d) gracile nucleus and cuneate nucleus.
10. The final relay point for ascending sensory information that will be projected to the primary sensory cortex is the (a) hypothalamus, (b) thalamus, (c) spinal cord, (d) medulla oblongata.
11. To which part of the brain is the pituitary gland connected? (a) pons, (b) thalamus, (c) midbrain, (d) hypothalamus.
12. Coordination of learned movement patterns at the subconscious level is performed by (a) the cerebellum, (b) the substantia nigra, (c) association fibers, (d) the hypothalamus.
13. The precentral gyrus and the postcentral gyrus appear the same and perform similar functions. (a) true, (b) false.
14. What are the primary cortical sensory association areas?

538 UNIT 3 Control and Regulation

15. Which three areas in the brain are not isolated from the general circulation by the blood-brain barrier?
16. List the names of the 12 pairs of cranial nerves. (*Hint: Use the mnemonic device "Oh, Once One Takes The Anatomy Final, Very Good Vacations Are Heavenly."*)

LEVEL 2 Reviewing Concepts

17. Why can the brain respond to stimuli with greater versatility than the spinal cord?
18. Briefly summarize the overall function of the cerebellum.
19. Of the following cranial nerves, only the _____ has its origin in the midbrain. **(a)** abducens, **(b)** trigeminal, **(c)** trochlear, **(d)** facial, **(e)** vestibulocochlear.
20. What problems can occur if the prefrontal cortex is damaged? What used to be the purpose of performing prefrontal lobotomy in the middle of the 20th century?
21. What varied roles does the hypothalamus play in the body?
22. How do lateral and medial geniculate bodies differ in function?
23. During a dissection of the brain, a student sees a pair of brightly colored nuclei in the floor of the midbrain. His notes tell him that these nuclei are controlled by information from the cerebrum and the cerebellum. Which nuclei are these and what is their function?
24. What are the principal functional differences between the right and left cerebral hemispheres?
25. The cerebral nucleus that plays a role in responding to fear and anxiety is the **(a)** putamen, **(b)** suprachiasmatic nucleus, **(c)** paraventricular nucleus, **(d)** hippocampus, **(e)** amygdaloid body.
26. Damage to the inferior olivary complex can hamper the relay of information from the **(a)** red nucleus, **(b)** solitary nucleus, **(c)** gracile nucleus, **(d)** cuneate nucleus, **(e)** vestibular nucleus.
27. Which structure, made of both white and grey matter with embedded nuclei, is involved in vital autonomic (breathing, blood pressure,

thermoregulation) and endocrine functions, and also affects body posture, skeletomuscular reflexes as well as alertness and sleep? Where in the brain is it located?

LEVEL 3 Critical Thinking and Clinical Applications

28. Smelling salts can sometimes help restore consciousness after a person has fainted. The active ingredient of smelling salts is ammonia, and it acts by irritating the lining of the nasal cavity. Propose a mechanism by which smelling salts would raise a person from the unconscious state to the conscious state.
29. A police officer has just stopped Elias on suspicion of driving while intoxicated. The officer asks Elias to walk the yellow line on the road and then to place the tip of his index finger on the tip of his nose. How would these activities indicate Elias's level of sobriety? Which part of the brain is being tested by these activities?
30. Olga is diagnosed with a benign tumor of the pituitary gland. The tumor is small but there is a fear that it will grow and start causing problems. A noninvasive way to follow the evolution of the tumor is to regularly measure the width of Olga's field of view. When the tumor grows, the field of view will narrow. Why is this?
31. Cerebral meningitis is a condition in which the meninges of the brain become inflamed as the result of viral or bacterial infection. This condition can be life threatening. Why?
32. Infants have little to no control of the movements of their head. One of the consequences of this is that they are susceptible to shaken baby syndrome, caused by vigorous shaking of an infant or young child by the arms, legs, chest, or shoulders. Forceful shaking can cause brain damage leading to mental retardation, speech and learning disabilities, paralysis, seizures, hearing loss, and even death. Damage to which areas of the brain would account for the clinical signs observed in this syndrome?

**CLINICAL CASE Wrap-Up The Bells!**

When Shane's MRI scan results were returned to the neurologist, they did not show any evidence of tumors or damage to his brain. His blood tests were also normal. In addition, the signs and symptoms he presented with, that is, the drooping face, lack of facial expression, inability to close his left eye, and loss of sensation, were all consistent with the cause being a problem with the function of cranial nerve VII, the facial nerve. This is the nerve which innervates all of Shane's affected facial muscles.

Putting together the evidence, the neurologist quickly came to the conclusion that Shane had not had a stroke but had rather been affected by Bell's Palsy. This is a condition where there is dysfunction of the facial nerve on one side of the body, leading to paralysis of facial muscles on the same side. No specific cause for Bell's Palsy

has yet been identified, although it is thought to be caused by inflammation of the facial nerve which may be associated with prior viral infections such as Shane's recent cough. The good news is that due to treatment with corticosteroids, Shane recovered fully, which is the case for 70–80% of people who have the condition.

1. If Shane had had a stroke, what area of the brain would most likely be damaged to give rise to similar signs and symptoms?
2. Bell's Palsy affected the left side of his face. Which facial nerve, left or right, was therefore affected?

See the blue Answers tab at the back of the book.

Related Clinical Terms

attention deficit hyperactivity disorder (ADHD): Disorder occurring mainly in children characterized by hyperactivity, inability to concentrate, and impulsive or inappropriate behavior.

autism: Any of a range of behavioral disorders occurring primarily in children, including such symptoms as poor concentration, hyperactivity, and impulsivity.

Creutzfeldt-Jakob disease (CJD): A rare, degenerative, invariably fatal brain disorder that is marked by rapid mental deterioration. The disease, which is caused by a prion (an infectious protein particle), typically starts by causing mental and emotional problems, then progresses to affect motor skills, such as walking and talking.

delirium: An acutely disturbed state of mind that occurs in fever, intoxication, and other disorders and is characterized by restlessness, hallucinations, and incoherence of thought and speech.

dementia: A chronic or persistent disorder of the mental processes caused by brain disease or injury and marked by memory disorders, personality changes, and impaired reasoning.

Glasgow coma scale: The most widely used scoring system to quantify the level of consciousness of a victim of a traumatic brain injury. It rates three functions: eye opening, verbal response, and motor response.

migraine: A type of headache marked by severe debilitating head pain lasting several hours or longer.

myoclonus: A quick, involuntary muscle jerk or contraction; persistent myoclonus usually indicates a nervous system disorder.

pallidectomy: The destruction of all or part of the globus pallidus by chemicals or freezing; used in the treatment of Parkinson's disease.

prosopagnosia: The inability to recognize other humans by their faces.

psychosis: A severe mental disorder in which thought and emotions are so impaired that contact with reality is lost.

stupor: A state of near-unconsciousness or insensibility.

transient ischemic attack (TIA): An episode in which a person has stroke-like symptoms that last less than 24 hours and result in no permanent injury to the brain but may be a warning sign of the potential for a major stroke.

15

Sensory Pathways and the Somatic Nervous System

Learning Outcomes

These Learning Outcomes correspond by number to this chapter's sections and indicate what you should be able to do after completing the chapter.

- 15-1 ■ Specify the components of the afferent and efferent divisions of the nervous system and explain what is meant by the somatic nervous system.
- 15-2 ■ Explain why receptors respond to specific stimuli, and how the organization of a receptor affects its sensitivity.
- 15-3 ■ Identify the receptors for the general senses and describe how they function.
- 15-4 ■ Identify the major sensory pathways and explain how it is possible to distinguish among sensations that originate in different areas of the body.
- 15-5 ■ Describe the components, processes, and functions of the somatic motor pathways, and the levels of information processing involved in motor control.

CLINICAL CASE

Living with Cerebral Palsy

Michael Ward had a challenging start in life. His mother had a difficult and prolonged labor in the days when cesarean sections were rarely performed. Michael was a large baby and was born with brain damage from inadequate oxygen during birth, requiring an extended resuscitation. The lack of oxygen to his brain caused a condition known as *cerebral palsy* (CP).

Michael was critically ill as a newborn and remained hospitalized for weeks. Because of swallowing difficulties, he had aspiration pneumonia (lung inflammation from inhaling food) three times in his first year of life. He was delayed in reaching gross and fine motor developmental milestones, and although he had plenty to say, his speech was difficult to understand. When he was finally able to walk, by age 4, he used crutches

or held a parent's hand. His gait was slow, unsteady, and crouched. He fell often. He has used a wheelchair regularly since high school.

Cerebral palsy is the most common congenital neurological condition, affecting as many as 1 million Americans. Despite advances in obstetric and neonatal care, the incidence of CP has not changed in the past half century. Cerebral palsy is caused by an injury to the developing brain and can occur before, during, or a few years after

birth. The specific signs and symptoms of the person with CP relate to the areas of the brain affected by the injury. It is not contagious. It is not progressive. It is a condition, not a disease.

How did Michael's life turn out? See the Clinical Case Wrap-Up at the end of the chapter.

An Introduction to Sensory Pathways and the Somatic Nervous System

In this chapter we examine how the nervous system works as an integrated unit. We first consider the sensory receptors and sensory processing centers in the brain that make up *sensory pathways*. In our discussion, we focus primarily on the *general senses* that provide information about the body and its environment, rather than the *special senses* such as sight and hearing. Most of the coverage of the special senses is in Chapter 17.

Then we look at the *motor pathways* that provide for the voluntary and involuntary motor functions of the nervous system. Motor commands issued by the CNS are distributed to the PNS by the *somatic nervous system* and the *autonomic nervous system*. The somatic nervous system (SNS) controls the contractions of skeletal muscles, and its output is under voluntary control. The autonomic nervous system (ANS), or *visceral motor system*, controls visceral effectors, such as smooth muscle, cardiac muscle, glands, and adipocytes. We examine the organization and functions of the ANS in Chapter 16.

15-1 Sensory stimuli cause signals to be sent along sensory pathways, and in response motor commands are sent along motor pathways

Learning Outcome Specify the components of the afferent and efferent divisions of the nervous system and explain what is meant by the somatic nervous system.

The basic events that occur along sensory and motor pathways are shown in **Figure 15-1**. Along **sensory pathways**, a series of

neurons relays sensory information from the initiating point (the sensory receptor) to its final destination inside the CNS. *Sensory receptors* are specialized cells or cell processes that monitor specific conditions in the body or the external environment. When stimulated, a receptor generates action potentials that are propagated along the axon of a sensory neuron and then relayed to other neurons within the pathway. This signal is finally delivered to the CNS, where it can be processed.

Taken together, the somatic and visceral sensory pathways make up the *afferent division* of the nervous system. Somatic and visceral sensory information often travels along the same pathway. Somatic sensory information is distributed to *sensory processing centers* in the brain—either the primary somatosensory cortex of the cerebral hemispheres or appropriate areas of the cerebellar hemispheres. Visceral sensory information is distributed primarily to reflex centers in the brainstem and diencephalon.

Once sensory information is integrated by the CNS, somatic (and visceral) motor commands may be issued. Somatic motor commands are carried out by the somatic motor portion of the *efferent division*—the *somatic motor pathways* that control peripheral effectors such as skeletal muscles (**Figure 15-1**). No matter where somatic motor commands arise—at the conscious (voluntary) or subconscious (involuntary) levels—they travel from motor centers in the brain along these somatic motor pathways. The motor neurons and pathways that control skeletal muscles form the somatic nervous system.

Motor commands may be modified by planning, memories, and learning—the so-called *higher-order functions* of the brain. Higher-order functions are also considered in Chapter 16.

Figure 15-1 An Overview of Events Occurring Along the Sensory and Motor Pathways.

Which motor pathway directs a faster response: voluntary or involuntary?

Checkpoint

1. What do we call the body's specialized cells that monitor specific internal or external conditions?
2. Is it possible for somatic motor commands to occur at the subconscious level?

See the blue Answers tab at the back of the book.

15-2 Sensory receptors connect our internal and external environments with the nervous system

Learning Outcome Explain why receptors respond to specific stimuli, and how the organization of a receptor affects its sensitivity.

As we noted, **sensory receptors** are either the processes of specialized sensory neurons or cells monitored by sensory neurons. These receptors provide the central nervous system with information about conditions inside or outside the body. General sensory receptors are scattered throughout the body. Some of the information they send to the CNS reaches

the primary somatosensory cortex and conscious awareness. The arriving information is called a **sensation**. The conscious awareness of a sensation is called a **perception**.

Our senses can be divided into general and special. We use the term **general senses** to describe our sensitivity to temperature, pain, touch, pressure, vibration, and *proprioception* (body position). The **special senses** are *olfaction* (smell), *gustation* (taste), *vision* (sight), *equilibrium* (balance), and *hearing*. These sensations are provided by receptors that are structurally more complex than those of the general senses. *Special sensory receptors* are located in **sense organs** such as the eye or ear, where surrounding tissues protect the receptors. The information these receptors provide is distributed to specific areas of the cerebral cortex (the olfactory cortex, the visual cortex, and so forth) and to centers throughout the brainstem. We discuss the common functions of both general and special sensory receptors here, and then go on to describe the specific function of each type of special sensory receptor in Chapter 17.

Sensory receptors represent the interface between the nervous system and the internal and external environments. When a sensory receptor detects an arriving stimulus and converts it

into an action potential that can be propagated to the CNS, this conversion process is called *transduction*. If transduction does not take place, then as far as the body is concerned, the stimulus doesn't exist. For example, bees can see ultraviolet light that humans can't see. Dogs can respond to sounds humans can't hear. In each case the stimuli are there—but the receptors cannot detect them. Now we examine the basic concepts of receptor function and sensory processing.

The Detection of Stimuli

How do receptors detect stimuli? Each receptor has a characteristic sensitivity. For example, a touch receptor is very sensitive to pressure but relatively insensitive to chemical stimuli. A taste receptor is sensitive to dissolved chemicals but insensitive to pressure. This feature is called *receptor specificity*.

Specificity may result from the structure of the receptor cell or from the presence of accessory cells or structures that shield the receptor cell from other stimuli. The simplest receptors are the dendrites of sensory neurons. The branching tips of these dendrites, called *free nerve endings*, are not protected by accessory structures. Free nerve endings extend through a tissue the way grass roots extend into the soil. Many different stimuli can stimulate them. For this reason, free nerve endings show little receptor specificity. For example, chemicals, pressure, temperature changes, or trauma may stimulate free nerve endings that respond to tissue damage by providing pain sensations.

Complex receptors, such as the eye's visual receptors, are protected by accessory cells and connective tissue layers. These cells are seldom exposed to any stimulus other than light and so provide very specific information.

Receptive Fields

The area monitored by a single receptor cell is its *receptive field* (Figure 15–2). Whenever a sufficiently strong stimulus arrives in the receptive field, the CNS receives the information “stimulus arriving at receptor X.” The larger the receptive field, the poorer the ability to localize a stimulus. A touch receptor on the general body surface, for example, may have a receptive field 7 cm (2.5 in.) in diameter. As a result, a person can describe a light touch there as affecting only a general area, not an exact spot. On the tongue or fingertips, the receptive fields are less than a millimeter in diameter. In these areas, humans can be very precise about the location of a stimulus.

The Process of Transduction

An arriving stimulus can take many forms. It may be a physical force (such as pressure), a dissolved chemical, a sound, or light. Regardless of the nature of the stimulus, however, sensory information is sent to the CNS only in the form of action potentials, which are electrical events.

Transduction is the conversion of an arriving stimulus into an action potential by a sensory receptor. Transduction

Figure 15–2 Receptors and Receptive Fields. Each receptor cell monitors a specific area known as the receptive field.

Describe a receptive field.

begins when a stimulus changes the membrane potential of the receptor cell. This change, called a *receptor potential*, is either a graded depolarization or a graded hyperpolarization. The stronger the stimulus, the larger the receptor potential.

The typical receptors for the general senses are the free nerve endings (dendrites) of sensory neurons. In these cases, the sensory neuron is the receptor cell. Any receptor potential that depolarizes the plasma membrane will bring the membrane closer to threshold. A depolarizing receptor potential in a neural receptor is called a *generator potential*.

Specialized receptor cells that communicate with sensory neurons across chemical synapses give us sensations of taste, hearing, equilibrium, and vision. In these cases, the receptor potential and the generator potential occur in different cells. The receptor potential develops in the receptor cell, and the generator potential appears later, in the sensory neuron. The receptor cells develop graded receptor potentials in response to stimulation, and the change in membrane potential alters the rate of neurotransmitter release at the synapse. The result is a depolarization or hyperpolarization of the sensory neuron. If sufficient depolarization occurs, an action potential appears in the sensory neuron.

Whenever a sufficiently large generator potential appears, action potentials develop in the axon of a sensory neuron. As discussed in Chapter 12, the greater the degree of sustained depolarization at the axon hillock, the higher the frequency of action potentials in the afferent fiber.

The Interpretation of Sensory Information

Sensory information that arrives at the CNS is routed according to the location and nature of the stimulus. In previous chapters we emphasized the fact that axons in the CNS are organized in tracts with specific origins and destinations. Once a receptor is stimulated, the series of neurons in that sensory pathway relay

that signal to a neuron at a specific site in the cerebral cortex. For example, sensations of touch, pressure, pain, and temperature arrive at the primary somatosensory cortex. Visual, auditory, gustatory (taste), and olfactory (smell) sensations reach their respective visual, auditory, gustatory, and olfactory regions of the cortex.

Determination of the Characteristics of Stimuli

The link between peripheral receptor and cortical neuron is called a **labeled line**. Each labeled line consists of axons carrying information about one *modality*, or type of stimulus (touch, pressure, light, or sound). The type of stimulus perceived by the CNS is determined by which labeled line is activated. For this reason, humans cannot feel the difference between a “true” sensation and a “false” one generated somewhere along the line. For example, when a person rubs their eyes, they commonly see flashes of light. The stimulus is mechanical (physical pressure) rather than visual, but *any* activity along the optic nerve is projected to the visual cortex. As a result, it is experienced as a visual perception.

15 All other characteristics of the stimulus—its strength, duration, and variation—are conveyed by the frequency and pattern of action potentials. As noted in Chapter 12, the CNS interprets sensory information based on the frequency of arriving action potentials. For example, when pressure sensations are arriving, the greater the pressure, the higher the frequency of action potentials. The conversion of complex sensory information into meaningful patterns of action potentials is called *sensory coding*.

Transduction in Tonic and Phasic Receptors

Receptors can be categorized by the nature of their response to stimulation (**Figure 15–3**). Some sensory neurons, called **tonic receptors**, are always active (**Figure 15–3a**). A *tonic response* is an increase or decrease in the frequency of action potentials

that directly reflects an increase or decrease in stimulation. Other receptors, called **phasic receptors**, are usually not active. Phasic receptors provide information about the intensity and rate of change of a stimulus (**Figure 15–3b**). A *phasic response* to stimulation begins with a burst of action potentials that ends when the stimulus stops or does not change in intensity. Receptors that combine phasic and tonic coding can convey extremely complicated sensory information.

Adaptation of Sensory Receptors

Adaptation is a reduction of receptor sensitivity in the presence of a constant stimulus. For example, people seldom notice the rumble of car tires when riding in a car or the background noise of an air conditioner. The reason is that the nervous system quickly adapts to stimuli that are painless and constant.

There are two types of sensory receptor adaptation: peripheral and central. *Peripheral adaptation* occurs in the PNS when the level of receptor activity changes. The receptor responds strongly at first, but then its activity gradually decreases, in part because the size of the generator potential gradually decreases. This response is characteristic of phasic receptors, which are also called **fast-adapting receptors**. For example, temperature receptors are phasic receptors, so one seldom notices the room temperature unless it changes suddenly.

Tonic receptors show little peripheral adaptation and so are called **slow-adapting receptors**. Pain receptors are slow-adapting receptors. This is one reason why pain sensations remind humans of an injury long after the initial damage has taken place.

Adaptation also occurs along sensory pathways inside the CNS. For example, a few seconds after exposure to a new smell, awareness of the stimulus virtually disappears, although the sensory neurons are still quite active. This process is known

Figure 15–3 Tonic and Phasic Sensory Receptors.

as *central adaptation*. Central adaptation generally involves the inhibition of nuclei along a sensory pathway.

Peripheral adaptation reduces the amount of information that reaches the CNS. Central adaptation at the subconscious level further restricts the amount of detail that arrives at the cerebral cortex. Most of the incoming sensory information is processed in centers along the spinal cord or brainstem at the subconscious level. This processing can produce reflexive motor responses, but people are seldom consciously aware of either the stimuli or the responses.

The output from higher centers can increase receptor sensitivity or help transmission along a sensory pathway. The reticular activating system in the midbrain helps focus attention and heightens or reduces awareness of arriving sensations. This adjustment of sensitivity can take place under conscious or subconscious direction. When “listening carefully,” sensitivity and awareness of auditory stimuli increase. Output from higher centers can also inhibit transmission along a sensory pathway. Such inhibition occurs when one enters a noisy factory or walks along a crowded city street. The high level of background noise is automatically tuned out. Next, we consider how these basic concepts of receptor function and sensory processing apply to the general senses.

Checkpoint

3. **Receptor A has a circular receptive field on the skin surface with a diameter of 2.5 cm. Receptor B has a circular receptive field 7.0 cm in diameter. Which receptor provides more precise sensory information?**
4. **Define adaptation.**

See the blue Answers tab at the back of the book.

15-3 General sensory receptors can be classified by the type of stimulus that excites them

Learning Outcome Identify the receptors for the general senses and describe how they function.

The receptors for the general senses are divided into three types by location of the stimulus. *Exteroceptors* provide information about the external environment. *Proprioceptors* report the positions and movements of skeletal muscles and joints. *Interoceptors* monitor visceral organs and functions.

However, other classification schemes for the general sensory receptors are also used. One useful scheme is to divide them into four types by the nature of the stimulus that excites them: *nociceptors* (pain), *thermoreceptors* (temperature), *mechanoreceptors* (physical distortion such as touch), and *chemoreceptors* (chemicals). Each class of receptors has distinct structural and functional characteristics, although all general sensory receptors are simple in structure.

There are both somatic and visceral versions of these receptors; the difference between them has to do with location, not structure. A pain receptor in the gut looks and acts like a pain receptor in the skin, but the two sensations are delivered to separate locations in the CNS. The visceral organs also have fewer pain, temperature, and touch receptors than we find elsewhere in the body. The sensory information received from these receptors is poorly localized because their receptive fields are very large and may be widely separated.

The processing of general sensations is widely distributed in the CNS, but most processing takes place in centers along the sensory pathways in the spinal cord or brainstem. Only about 1% of the information provided by afferent fibers reaches the cerebral cortex and our awareness. For example, a person usually does not feel the clothes they wear.

Let's take a closer look at the structure and function of the receptors as classified by the nature of their stimuli.

Nociceptors and Pain

Nociceptors (*noxa*, harm), or pain receptors, are especially common in the superficial portions of the skin, in joint capsules, within the periosteum of bones, and around the walls of blood vessels. Other deep tissues and most visceral organs have few nociceptors. Pain receptors are free nerve endings with large receptive fields (Figure 15-2). As a result, it is often difficult to determine the exact source of a painful sensation.

Different nociceptors may be sensitive to (1) temperature extremes, (2) mechanical damage, and (3) dissolved chemicals, such as chemicals released by injured cells. Very strong stimuli, however, will excite all three receptor types. For that reason, people describing very painful sensations—whether caused by acids, heat, or a deep cut—use similar descriptive terms, such as “burning.”

Stimulation of the dendrites of a nociceptor causes depolarization. When the initial segment of the axon reaches threshold, an action potential travels toward the CNS.

Types of Pain

Two types of axons—Type A and Type C fibers—carry painful sensations. Myelinated Type A fibers carry sensations of **fast pain**, or *prickling pain*. An injection or a deep cut produces this type of pain. These sensations reach the CNS quickly, where they often trigger somatic reflexes. They are also relayed to the primary somatosensory cortex and so receive conscious attention. In most cases, the arriving information allows stimulus localization to an area several inches in diameter.

Unmyelinated Type C fibers carry sensations of **slow pain**, or *burning and aching pain*. These sensations cause a generalized activation of the reticular formation and thalamus. A person becomes aware of the pain, but they have only a general idea of the area affected.

Pain Perception

Nociceptors are tonic receptors (Figure 15-3a). Significant peripheral adaptation does not occur in these receptors, so they continue to respond if the painful stimulus remains. Painful sensations stop only after tissue damage has ended. However, central adaptation may reduce the *perception* of the pain while nociceptors remain stimulated. This effect involves the inhibition of centers in the thalamus, reticular formation, lower brainstem, and spinal cord.

An understanding of the origins of pain sensations and an ability to control or reduce pain levels have always been among the most important aspects of medical treatment. After all, it is usually pain that causes us to seek treatment. We usually tolerate or ignore conditions that are not painful. Although we often use the term *pain pathways* to refer to the route on which pain signals travel to the brain, pain distribution and perception are extremely complex.

The sensory neurons that bring pain sensations into the CNS release *glutamate* and/or *substance P* as neurotransmitters. These neurotransmitters facilitate neurons along the pain pathways. As a result, the level of pain experienced (especially chronic pain) can be out of proportion to the amount of painful stimuli or the apparent tissue damage. This effect may be one reason why people differ so widely in their perception of the pain associated with headaches, back pain, or childbirth. This facilitation is also presumed to play a role in *phantom limb syndrome*, when pain is still felt in an amputated limb (discussed in Section 15-4): The sensory neurons may be inactive, but the hyperexcitable interneurons may continue to generate pain sensations.

The release of the neuromodulators called endorphins and enkephalins within the CNS can reduce the level of pain that a person feels. As noted in Chapter 12, endorphins and enkephalins, which are structurally similar to morphine, inhibit activity along pain pathways in the brain. They are found in the limbic system, hypothalamus, and reticular formation.

Tips

The **P** in substance **P** stands for **p**eptide and is involved with **p**ain, which it transmits **p**eripherally.

Thermoreceptors

Thermoreceptors, or temperature receptors, are free nerve endings located in the dermis, skeletal muscles, liver, and hypothalamus. Cold receptors are three or four times more numerous than warm receptors. There are no structural differences between warm and cold thermoreceptors. Temperature sensations are conducted along the same pathways that carry pain sensations. They are sent to the reticular formation, the thalamus, and (to a lesser extent) the primary somatosensory cortex.

Thermoreceptors are phasic receptors (Figure 15-3b). They are very active when the temperature is changing, but they quickly adapt to a stable temperature. Therefore, when entering an air-conditioned classroom on a hot summer day, the temperature change seems extreme at first, but as adaptation occurs, the temperature becomes comfortable.

Mechanoreceptors

Mechanoreceptors (MEK-ah-nō-rē-sep-terz) are sensitive to physical stimuli that distort their plasma membranes. These membranes contain *mechanically gated ion channels*. The gates open or close in response to stretching, compression, twisting, or other distortions of the membrane.

There are three classes of mechanoreceptors: tactile receptors, baroreceptors, and proprioceptors.

- **Tactile receptors** provide the closely related sensations of touch, pressure, and vibration. Touch sensations provide information about shape or texture, whereas pressure sensations indicate the degree of mechanical distortion. Vibration sensations indicate a pulsing pressure. The receptors involved may be specialized in some way. For example, rapidly adapting tactile receptors are best suited for detecting vibration. But interpretation of a sensation as touch rather than pressure is typically a matter of the degree of stimulation, and not of differences in the type of receptor stimulated.
- **Baroreceptors** (bar-ō-rē-SEP-terz; *baro-*, pressure) detect pressure changes in the walls of blood vessels and in portions of the digestive, respiratory, and urinary tracts.
- **Proprioceptors** monitor the positions of joints and skeletal muscles. They are the most structurally and functionally complex of the general sensory receptors.

Tactile Receptors

Fine touch and pressure receptors provide detailed information about a source of stimulation, including its exact location, shape, size, texture, and direction of movement. These receptors are extremely sensitive and have narrow receptive fields. In contrast, *crude touch and pressure receptors* provide poor localization. They give little additional information about the stimulus because they have large receptive fields.

Tactile receptors range in complexity from free nerve endings to specialized sensory complexes with accessory cells and supporting structures. Figure 15-4 shows six types of tactile receptors in the skin: free nerve endings, root hair plexuses, tactile discs, bulbous corpuscles, lamellar corpuscles, and tactile corpuscles.

- *Free nerve endings* sensitive to touch and pressure are located between epidermal cells (Figure 15-4a). Free nerve endings that provide touch sensations are tonic receptors with small receptive fields. There appear to be no structural differences between these receptors and the free nerve

Figure 15–4 Tactile Receptors in the Skin.

Which tactile receptors are located in the dermis?

endings that provide temperature or pain sensations. These are the only sensory receptors on the corneal surface of the eye, but in other portions of the body surface, more specialized tactile receptors are probably more important.

- Wherever hairs are located, the nerve endings of the **root hair plexus** monitor distortions and movements across the body surface (**Figure 15-4b**). When a hair is displaced, the movement of its follicle distorts the sensory dendrites and produces action potentials. These receptors adapt rapidly, so they are best at detecting initial contact and subsequent movements. For example, a person generally feels their clothing only when they move or when they consciously focus on tactile sensations from their skin.
- **Tactile discs** are fine-touch and pressure receptors sensitive to shape and texture (**Figure 15-4c**). They are extremely sensitive tonic receptors, with very small receptive fields. The flattened dendritic processes of a single myelinated afferent fiber make close contact with unusually large epithelial cells in the stratum basale of the skin, as described in Chapter 5.
- **Bulbous corpuscles** (KOR-pus-elz), also called *Ruffini corpuscles*, are sensitive to pressure and distortion of the skin, and they are in the reticular (deep) dermis. These receptors are tonic and show little if any adaptation. The capsule surrounds a core of collagen fibers that are continuous with those of the surrounding dermis (**Figure 15-4d**). In the capsule, a network of dendrites is intertwined with the collagen fibers. Any tension or distortion of the dermis tugs or twists these fibers, stretching or compressing the attached dendrites and altering the activity in the myelinated afferent nerve fiber.
- **Lamellar (LAM-eh-lar) corpuscles**, also called *Pacinian corpuscles*, are sensitive to deep pressure. Because they are fast-adapting receptors, they are most sensitive to pulsing or high-frequency vibrating stimuli. These relatively large corpuscles may reach 4 mm in length and 1 mm in diameter. In these corpuscles, a single dendrite lies within a series of concentric layers of collagen fibers and supporting cells (specialized fibroblasts) (**Figure 15-4e**). The concentric layers, separated by interstitial fluid, shield the dendrite from virtually every source of stimulation other than direct pressure. Lamellar corpuscles adapt quickly because distortion of the capsule soon relieves pressure on the sensory process. Somatic sensory information is provided by lamellar corpuscles located throughout the dermis, in the superficial and deep fasciae, and in joint capsules. Visceral sensory information is provided by lamellar corpuscles in the pancreas and the walls of the urethra and urinary bladder.
- **Tactile corpuscles**, also called *Meissner corpuscles*, give us sensations of fine touch and pressure and low-frequency vibration. They adapt to stimulation within a second after

contact. Tactile corpuscles are large structures, measuring about 100 μm in length and 50 μm in width. These receptors are most abundant in the eyelids, lips, fingertips, nipples, and external genitalia. The dendrites are highly coiled and interwoven, and modified Schwann cells surround them. A fibrous capsule surrounds the entire complex and anchors it within the dermis (**Figure 15-4f**).

Sensitivity to tactile sensations may be altered by infection, disease, or damage to sensory neurons or pathways. For this reason, mapping tactile responses can sometimes aid clinical assessment. Sensory losses with clear regional boundaries indicate trauma to spinal nerves. For example, sensory loss within the boundaries of a dermatome can help identify the affected spinal nerve.

Tickle and itch sensations are closely related to the sensations of touch and pain. The receptors involved are free nerve endings. Unmyelinated Type C fibers carry the information. People usually (but not always) describe tickle sensations as pleasurable. A light touch that moves across the skin typically produces a tickle sensation. Psychological factors influence the interpretation of tickle sensations, and tickle sensitivity differs greatly from person to person.

Itching is probably produced by the stimulation of the same receptors, although its precise mechanism is unknown. Specific “itch spots” can be mapped in the skin, the inner surfaces of the eyelids, and the mucous membrane of the nose. Itch sensations are absent from other mucous membranes and from deep tissues and viscera. Itching is very unpleasant, sometimes even more unpleasant than pain, as individuals with extreme itching will scratch even when pain is the result. Itch receptors can be stimulated by the injection of histamine or proteolytic enzymes into the epidermis and superficial dermis.

Baroreceptors

Baroreceptors monitor pressure changes in an organ. A baroreceptor consists of free nerve endings that branch within the elastic tissues in the wall of a distensible organ, such as a blood vessel or a portion of the respiratory, digestive, or urinary tract. When the pressure changes, the elastic walls of the tract recoil or expand. This movement distorts the dendritic branches and alters the rate of action potential generation. Baroreceptors respond immediately to a change in pressure, but they adapt rapidly, and the output along the afferent fibers gradually returns to normal.

Baroreceptors monitor pressure changes in organs that stretch due to their contents, such as blood, air, or urine. Baroreceptors monitor blood pressure in the walls of major vessels. These vessels include the carotid arteries (at the *carotid sinuses*) and the aorta arch. The information plays a major role in regulating cardiac function and adjusting blood flow to vital tissues. Baroreceptors in the lungs monitor lung expansion. This information is relayed to the respiratory rhythmicity

centers, which set the pace of breathing. Stretch receptors at various sites in the digestive and urinary tracts trigger a variety of visceral reflexes, including defecation and urination reflexes (**Figure 15-5**). We describe baroreceptor reflexes in the digestive and urinary system chapters.

Proprioceptors

Proprioception is a somatic sensation—there are no proprioceptors in visceral organs of the thoracic and abdominopelvic cavities. (Therefore, a person cannot feel, for example, where their spleen, appendix, or pancreas is now.) Proprioceptors are found in joints, tendons, and muscles, however. These receptors monitor the position of joints, the tension in tendons and ligaments, and the state of muscular contraction.

There are three major groups of proprioceptors:

- **Muscle Spindles.** As discussed in Chapter 13, **muscle spindles** monitor skeletal muscle length and trigger stretch reflexes.
- **Golgi Tendon Organs.** **Golgi tendon organs** are similar in function to bulbous corpuscles but are located at the junction

between a skeletal muscle and its tendon. In a Golgi tendon organ, dendrites branch repeatedly and wind around the densely packed collagen fibers of the tendon. These receptors are stimulated by tension in the tendon. They monitor the external tension developed during muscle contraction.

- **Receptors in Joint Capsules.** Joint capsules are richly innervated by free nerve endings that detect pressure, tension, and movement at the joint.

The sense of body position results from the integration of information from joint capsule receptors, muscle spindles, Golgi tendon organs, and the receptors of the internal ear.

Proprioceptors do not adapt to constant stimulation, and each receptor continuously sends information to the CNS. Most proprioceptive information is processed at subconscious levels. Only a small proportion of the arriving proprioceptive information reaches awareness.

Chemoreceptors

Chemoreceptors (KĒ-mō-rē-sep-terz) are specialized nerve cells that detect small changes in the concentration of specific chemicals or compounds. In general, chemoreceptors respond only to water-soluble and lipid-soluble substances that are dissolved in body fluids [interstitial fluid, blood plasma, and cerebrospinal fluid (CSF)]. These receptors exhibit peripheral adaptation over a period of seconds, although they may also show central adaptation.

The chemoreceptors included in the general senses do not send information to the primary somatosensory cortex, so a person is not consciously aware of the sensations they provide. The arriving sensory information is routed to brainstem centers that deal with the autonomic control of respiratory and cardiovascular functions. Neurons in the respiratory centers of the brain respond to the concentrations of hydrogen ions (pH) and carbon dioxide molecules in the CSF.

Chemoreceptors are also located in the **carotid bodies**, near the origin of the internal carotid arteries on each side of the neck, and in the **aortic bodies**, between the major branches of the aortic arch. (The carotid bodies and aortic bodies are small tissue masses of receptors and supporting cells.) These receptors monitor the pH and the carbon dioxide and oxygen levels in arterial blood and play an important role in the reflexive control of breathing and cardiovascular function. The afferent fibers leaving the carotid or aortic bodies reach the respiratory centers by traveling within cranial nerve IX (glossopharyngeal) and cranial nerve X (vagus) (**Figure 15-6**).

✓ Checkpoint

5. List the major types of general sensory receptors and identify the nature of the stimulus that excites each type.
6. Identify the three classes of mechanoreceptors.
7. What would happen to a person if the information from proprioceptors in their legs were blocked from reaching the CNS?

See the blue Answers tab at the back of the book.

15-4 The afferent division is made up of separate somatic sensory and visceral sensory pathways that deliver sensory information to the CNS

Learning Outcome Identify the major sensory pathways and explain how it is possible to distinguish among sensations that originate in different areas of the body.

When a sensory signal is being sent to the CNS along a sensory pathway, it goes through a series of neurons that can be distinguished by their locations. A sensory neuron that delivers sensations directly to the CNS is called a **first-order neuron**. The cell body of a first-order general sensory neuron is located in a spinal ganglion or cranial nerve ganglion. In the CNS, the axon of that sensory neuron synapses (passes signals to) on an interneuron known as a **second-order neuron**, which may be located in the spinal cord or brainstem. For us to become aware of the sensation, the second-order neuron in turn must pass on the signal to a **third-order neuron** in the thalamus.

Somewhere along its length, the axon of the second-order neuron crosses over to the opposite side of the CNS in a process

called **decussation**. As a result, the right side of the thalamus receives sensory information from the left side of the body, and the left side of the thalamus receives sensory information from the right side. The axon of the third-order neuron then ascends (without crossing back over) and synapses on neurons of the primary somatosensory cortex. Therefore, the right cerebral hemisphere receives sensory information from the left side of the body, and the left cerebral hemisphere receives sensations from the right side.

Our sensory pathways all include first-, second-, and third-order neurons. However, several different pathways bring somatic and visceral sensory information to the CNS. Let's look at some major representatives of each type.

Somatic Sensory Pathways

Somatic sensory pathways carry sensory information from the skin and muscles of the body wall, head, neck, and limbs to the CNS. We will consider three major somatic sensory pathways: (1) the *spinothalamic pathway*, (2) the *posterior column pathway*, and (3) the *spinocerebellar pathway*.

These pathways are made up of pairs of spinal tracts, symmetrically arranged on opposite sides of the spinal cord. All the axons within a tract share a common origin and destination. **Figure 15-7** shows the relative positions of the spinal tracts in each of these somatic sensory pathways.

Note that tract names often give clues to their function. For example, if the name of a tract begins with *spino-*, the tract *starts* in the spinal cord and *ends* in the brain. It must therefore be an ascending tract that carries sensory information. The rest of the name indicates the tract's destination. Thus, a *spinothalamic tract* begins in the spinal cord and carries sensory information to the thalamus.

+ Clinical Note Assessment of Tactile Sensitivities

Regional sensitivity to light touch can be checked by gentle contact with a fingertip or a slender wisp of cotton. The **two-point discrimination test** provides a more detailed sensory map of tactile receptors. Two fine points of a bent paper clip or another object are applied to the skin surface simultaneously. The person then describes the contact. When the points fall within a single receptive field, the person will report only one point of contact. A person usually loses two-point discrimination at 1 mm (0.04 in.) on the surface of the tongue, at 2–3 mm (0.08–0.12 in.) on the lips, at 3–5 mm (0.12–0.20 in.) on the backs of the hands and feet, and at 4–7 cm (1.6–2.75 in.) over the general body surface.

Applying the base of a tuning fork to the skin tests vibration receptors. Damage to an individual spinal nerve produces insensitivity to vibration along the paths of the related sensory nerves.

If the sensory loss results from spinal cord damage, the injury site can typically be located by walking the tuning fork down the spinal column, resting its base on the vertebral spinous processes.

Various descriptive terms indicate the degree of sensitivity in an area. *Anesthesia* implies a total loss of sensation. The person cannot perceive touch, pressure, pain, or temperature sensations in that area. *Paresthesia* is the presence of abnormal sensations such as the prickling sensation when an arm or leg “falls asleep” because of pressure on a peripheral nerve.

Figure 15–7 Sensory Pathways and Ascending Tracts in the Spinal Cord. A cross-sectional view of the spinal cord showing the locations of the major ascending (sensory) tracts.

Which pathway carries sensations of pain and temperature?

The Spinothalamic Pathway

The **spinothalamic pathway** carries sensations of crude touch, pressure, pain, and temperature. This pathway includes larger tracts that carry sensations destined for the cerebral cortex as well as small tracts that deliver sensations to reflex centers in the brainstem. We will ignore the smaller tracts in this discussion.

The larger tracts are the **anterior spinothalamic tract** and the **lateral spinothalamic tract**. Sensations bound for

the cerebral cortex ascend within these tracts, which end at third-order neurons in the ventral nuclei of the thalamus. After the sensations have been sorted and processed, they are relayed to the primary somatosensory cortex (**Spotlight Figure 15–8a**).

How we perceive an arriving stimulus, whether as painful, cold, hot, or vibrating, depends on which second-order and third-order neurons are stimulated. The ability to connect that stimulus with a specific location in the body—to *localize* the sensation—depends on the projection of information from the thalamus to an appropriate area of the primary somatosensory cortex.

Any abnormality along the pathway can result in inappropriate sensations or inaccurate localization of the source. Consider these examples:

- A person can experience painful sensations that are not produced where they are perceived to originate. For example, a person may continue to experience pain in an amputated limb. This **phantom limb syndrome** is caused by activity in the sensory neurons or interneurons along the spinothalamic pathway. The neurons involved were once part of the labeled line that monitored conditions in the intact limb. These labeled lines and pathways are developmentally programmed. For this reason, even people born without limbs can have phantom limb syndrome.
- A person can feel pain in an uninjured part of the body when the pain actually originates at another location, a phenomenon called **referred pain**. This occurs because the body surface is innervated by the same spinal segments. For example, strong visceral pain sensations arriving at a segment of the spinal cord can stimulate interneurons that are part of the spinothalamic pathway. Activity in these interneurons leads to the stimulation of the primary somatosensory cortex, so the individual feels referred pain in a specific part of the body.

a SPINOTHALAMIC PATHWAY

The **spinothalamic pathway** provides conscious sensations of poorly localized (“crude”) touch, pressure, pain, and temperature. In this pathway, the axons of first-order neurons enter the spinal cord and synapse on second-order neurons within the posterior horns. The axons of these interneurons cross to the opposite side of the spinal cord before ascending to the thalamus. The third-order neuron synapses in the primary somatosensory cortex.

KEY

- ➔ Axon of first-order neuron
- ➔ Second-order neuron
- ➔ Third-order neuron

A Sensory Homunculus

The functional mapping of the somatosensory cortex is called **somatotopy**. Such a somatotopic map is called a *homunculus*, meaning “little man” – as in, the little man in the brain. The map looks like a caricature, showing the relative size of cortex devoted to a particular body region is proportional to the density of sensory input received from that body region.

b POSTERIOR COLUMN PATHWAY

The **posterior column pathway** carries sensations of highly localized (“fine”) touch, pressure, vibration, and proprioception. This pathway is also known as the posterior column–medial lemniscus pathway. It begins at a peripheral receptor and ends at the primary somatosensory cortex of the cerebral hemispheres.

Fine touch, vibration, pressure, and proprioception sensations from right side of body

c SPINOCEREBELLAR PATHWAY

The cerebellum receives proprioceptive information about the position of skeletal muscles, tendons, and joints along the **spinocerebellar pathway**. The **posterior spinocerebellar tracts** contain axons that do not cross over to the opposite side of the spinal cord. These axons reach the cerebellar cortex by the inferior cerebellar peduncle of that side. The **anterior spinocerebellar tracts** are dominated by axons that cross over twice, in the spinal cord and then in the brainstem.

Proprioceptive input from Golgi tendon organs, muscle spindles, and joint capsule receptors

One familiar example is the pain of a heart attack, which is frequently felt in the left arm. Women are more likely than men to experience shortness of breath, nausea, vomiting, back pain, or jaw pain. Additional examples for both anterior and posterior sides of the body are shown in **Figure 15–9**.

The Posterior Column Pathway

The **posterior column pathway**, shown in **Spotlight Figure 15–8b**, carries sensations of fine touch, vibration, pressure, and proprioception. The spinal tracts involved are the left and right **gracile fasciculus** (*gracilis*, slender) and the left and right **cuneate fasciculus** (*cuneus*, wedge shaped). On each side of the posterior median sulcus, the gracile fasciculus is medial to the cuneate fasciculus (**Figure 15–7**).

The axons of the first-order neurons reach the CNS within the posterior roots of spinal nerves and the sensory roots of cranial nerves. The axons ascending within the posterior column are organized according to the region innervated. Axons carrying sensations from the inferior half of the body ascend within the gracile fasciculus and synapse in the gracile nucleus of the medulla oblongata. Axons carrying sensations from the superior half of the trunk, upper limbs, and neck ascend in the cuneate fasciculus and synapse in the cuneate nucleus.

Figure 15–9 Referred Pain. Pain sensations from visceral organs are often perceived as arising from areas distant from the actual origin (arrows). Each region of perceived pain is labeled according to the organ at which the pain originates.

Clinical Note Phantom Limb Syndrome

A soldier in combat unwittingly steps on a landmine. Although he survives, he loses his leg. During his extended rehabilitation he is at risk for a curious phenomenon called *phantom limb syndrome*. His leg—the one he lost—keeps him up at night with pain. Sometimes the leg burns; other times it feels like pins and needles. He says this leg feels touch, pressure, and vibration. It even itches! Despite the amputation, the sensory pathway for this leg persists and continues to convey messages to the thalamus. If the veteran is fit for a prosthesis (an artificial limb replacement) and wears it early and regularly, the device will ease his phantom limb pain by applying a real physical stimulus to the limb stump.

Axons of the second-order neurons of the gracile nucleus and cuneate nucleus decussate in the brainstem as they ascend toward the thalamus. Once on the opposite side of the brain, the axons enter a tract called the **medial lemniscus** (*lemniskos*, ribbon). The axons in this tract synapse on third-order neurons in one of the ventral nuclei of the thalamus. These nuclei sort the arriving information according to (1) the nature of the stimulus and (2) the region of the body involved. Processing in the thalamus determines whether a given sensation is perceived as fine touch, pressure, or vibration.

The sensation is then localized by where it arrives in the primary somatosensory cortex. Sensory information from the toes arrives at the medial end of the primary sensory cortex, and information from the head arrives at the lateral end. When neurons in one portion of the primary somatosensory cortex are stimulated, a person becomes aware of sensations originating at a specific location.

The Sensory Homunculus

The same sensations are reported whether the cortical neurons are activated by axons ascending from the thalamus or by direct electrical stimulation. Researchers have electrically stimulated the primary somatosensory cortex in awake individuals during brain surgery and asked the subjects where they thought the stimulus originated. The results were used to create a functional map of the primary somatosensory cortex known as a *sensory homunculus*.

In a sensory homunculus, the body features are distorted. For example, the face is huge, with enormous lips and tongue, but the back is relatively tiny. These distortions arise because the area of somatosensory cortex devoted to a particular body region is proportional to the density of *sensory neurons* in the region, not to the region's physical size. In other words, many more cortical neurons are required to process sensory information from the tongue, which has tens of thousands of taste and touch receptors, than to process sensations from the back, where touch receptors are few and far between.

The Spinocerebellar Pathway

The **spinocerebellar pathway** conveys information about muscle, tendon, and joint positions from the spine to the cerebellum (**Spotlight Figure 15–8c**). This information does not reach our awareness. The axons of first-order sensory neurons synapse on interneurons in the posterior horns of the spinal cord. The axons of these second-order neurons ascend in one of the spinocerebellar tracts: the **posterior spinocerebellar tracts** or the **anterior spinocerebellar tracts**.

The sensations carried by the anterior spinocerebellar tracts reach the cerebellar cortex by the superior cerebellar peduncle. Interestingly, many of the axons that cross over and ascend to the cerebellum then cross over again within the cerebellum, synapsing on the same side as the original stimulus. The functional significance of this “double cross” is unknown.

The information carried by the spinocerebellar pathway ultimately arrives at the *Purkinje cells* of the cerebellar cortex. Proprioceptive information from each part of the body is relayed to a specific portion of the cerebellar cortex. We consider the integration of proprioceptive information and the role of the cerebellum in somatic motor control in Section 15-5.

Visceral Sensory Pathways

Visceral sensory information is collected by interoceptors monitoring visceral tissues and organs, primarily within the thoracic and abdominopelvic cavities. These interoceptors include nociceptors, thermoreceptors, tactile receptors, baroreceptors, and chemoreceptors, although none of them is as numerous as they are in somatic tissues.

Sensory information from these interoceptors is carried from the mouth, palate, pharynx, larynx, trachea, esophagus, and associated vessels and glands by cranial nerves V, VII, IX, and X. The posterior roots of spinal nerves T_1 – L_2 carry visceral sensory information provided by receptors in organs located between the diaphragm and the pelvic cavity. The posterior roots of spinal nerves S_2 – S_4 carry visceral sensory information from organs in the inferior pelvic cavity. These organs include the last segment of the large intestine, the urethra and base of the urinary bladder, and the prostate (males) or the cervix of the uterus and portions of the vagina (females).

The axons of first-order neurons that carry visceral sensory information usually travel in company with autonomic motor fibers innervating the same visceral structures. These first-order neurons deliver the sensory information to second-order interneurons whose axons ascend within the spinothalamic pathway. Most of this information is delivered to the **solitary nucleus**, a large nucleus on each side of the medulla oblongata that has extensive connections with the various cardiovascular and respiratory centers as well as with the reticular formation. These connections allow the solitary nuclei to function as major processing and sorting centers for visceral sensory information. Because there is no third-order neuron in this pathway, this

sensory information never reaches the primary sensory cortex, and a person remains unaware of these sensations.

Table 15–1 summarizes the somatic sensory pathways discussed in this section.

✓ Checkpoint

8. As a result of pressure on her spinal cord, Jill cannot feel fine touch or pressure on her lower limbs. Which spinal tract is being compressed?
9. Which spinal tract carries action potentials generated by nociceptors?
10. Which cerebral hemisphere receives impulses carried by the right gracile fasciculus?

See the blue Answers tab at the back of the book.

15-5 The somatic nervous system is an efferent division made up of somatic motor pathways that control skeletal muscles

Learning Outcome Describe the components, processes, and functions of the somatic motor pathways, and the levels of information processing involved in motor control.

Now we look at the structure of the **somatic nervous system (SNS)**, which controls skeletal muscles. The SNS is made up of **somatic motor pathways** that consist of motor nuclei, tracts, and nerves. Throughout this discussion we use the terms *motor neuron* and *motor control* to refer specifically to these somatic motor neurons and pathways.

Somatic motor pathways always involve at least two motor neurons: an **upper motor neuron**, whose cell body lies in a CNS processing center (the premotor and/or primary motor cortexes), and a **lower motor neuron**, whose cell body lies in a nucleus of the brainstem or spinal cord. Only the axon of the lower motor neuron extends outside the CNS. The upper motor neuron synapses on the lower motor neuron, which in turn innervates a single motor unit in a skeletal muscle.

Activity in the upper motor neuron may facilitate or inhibit the lower motor neuron. Activation of the lower motor neuron triggers a contraction in the innervated muscle. Destruction of or damage to a lower motor neuron eliminates voluntary and reflex control over the innervated motor unit.

Figure 15–10 indicates the positions of the associated motor (descending) tracts in the spinal cord. Conscious and subconscious motor commands control skeletal muscles by traveling over three integrated motor pathways: the *corticospinal pathway*, the *medial pathway*, and the *lateral pathway*. Note that because the name of the corticospinal tract ends in *-spinal*, this indicates that the tract ends in the spinal cord. The first part of the name indicates the nucleus or cortical area of the brain where the tract originates. Therefore, the name of the corticospinal tract indicates that it carries motor commands from the cerebral cortex to the spinal cord.

Table 15–1 Ascending (Sensory) Pathways

		Location of Neuron Cell Bodies			Location of Neuron Cell Bodies	
Pathway/Tract	Sensation(s)	First-Order	Second-Order	Third-Order	Destination	Site of Decussation
SPINOTHALAMIC PATHWAY						
Lateral spinothalamic tracts	Pain and temperature	Spinal ganglia; axons enter CNS in posterior roots	Interneurons in posterior horn; axons enter lateral spinothalamic tract on opposite side	Ventral nuclei of thalamus	Primary sensory cortex on side opposite stimulus	Axons of second-order neurons at level of entry
Anterior spinothalamic tracts	Crude touch and pressure	Spinal ganglia; axons enter CNS in posterior roots	Interneurons in posterior horn; axons enter anterior spinothalamic tract on opposite side	Ventral nuclei of thalamus	Primary sensory cortex on side opposite stimulus	Axons of second-order neurons at level of entry
POSTERIOR COLUMN PATHWAY						
Gracile fasciculus	Proprioception and fine touch, anterior pressure, and vibration from inferior half of body	Spinal ganglia of inferior half of body; axons enter CNS in posterior roots and join gracile fasciculus	Gracile nucleus of medulla oblongata; axons cross over before entering medial lemniscus	Ventral nuclei of thalamus	Primary sensory cortex on side opposite stimulus	Axons of second-order neurons before entering the medial lemniscus
Cuneate fasciculus	Proprioception and fine touch, anterior pressure, and vibration from superior half of body	Spinal ganglia of superior half of body; axons enter CNS in posterior roots and join cuneate fasciculus	Cuneate nucleus of medulla oblongata; axons cross over before entering medial lemniscus	Ventral nuclei of thalamus	Primary sensory cortex on side opposite stimulus	Axons of second-order neurons before entering the medial lemniscus
SPINOCEREBELLAR PATHWAY						
Posterior spinocerebellar tracts	Proprioception	Spinal ganglia; axons enter CNS in posterior roots	Interneurons in posterior horn; axons enter posterior spinothalamic tract on same side	Not present	Cerebellar cortex on side of stimulus	None
Anterior spinocerebellar tracts	Proprioception	Spinal ganglia; axons enter CNS in posterior roots	Interneurons in same spinal section; axons enter anterior spinocerebellar tract on the same or opposite side	Not present	Cerebellar cortex on side opposite (and side of) stimulus	Axons of most second-order neurons cross over before entering tract; many recross at cerebellum

The basal nuclei and cerebellum monitor and adjust activity within these motor pathways. The output of these centers stimulates or inhibits the activity of either (1) motor nuclei or (2) the primary motor cortex. Next, we learn about these motor pathways and how they are monitored.

The Corticospinal Pathway

The **corticospinal pathway** (Figure 15–11), sometimes called the *pyramidal system*, provides voluntary control over skeletal muscles. This system begins at the *pyramidal cells* of the primary motor cortex. The axons of these upper motor neurons descend into the brainstem and spinal cord to synapse on lower motor neurons that control skeletal muscles. In general, the corticospinal pathway is direct: The upper motor neurons synapse directly on the lower motor neurons. However, the corticospinal pathway also works indirectly, as it innervates centers of the medial and lateral pathways.

The corticospinal pathway contains three pairs of descending tracts: (1) the *corticobulbar tracts*, (2) the *lateral corticospinal tracts*, and (3) the *anterior corticospinal tracts*. These tracts enter the white matter of the internal capsule, descend into the brainstem, and emerge on either side of the midbrain as the *cerebral peduncles*.

The Corticobulbar Tracts

Axons in the **corticobulbar** (kor-ti-kō-BUL-bar; *bulbar*, brainstem) **tracts** synapse on lower motor neurons in the motor nuclei of cranial nerves III, IV, V, VI, VII, IX, XI, and XII. The corticobulbar tracts provide conscious control over skeletal muscles that move the eyes, jaw, and face and some muscles of the neck and pharynx. The corticobulbar tracts also innervate the motor centers of the medial and lateral pathways.

The Corticospinal Tracts

Axons in the **corticospinal tracts** synapse on lower motor neurons in the anterior horns of the spinal cord. As they descend, the

Figure 15–10 Descending (Motor) Tracts in the Spinal Cord. A cross-sectional view showing the locations of the major descending (motor) tracts that contain the axons of upper motor neurons.

Identify the descending (motor) tracts in the spinal cord.

corticospinal tracts are visible along the anterior surface of the medulla oblongata as a pair of thick bands, the **pyramids** (which is why these tracts are sometimes called the *pyramidal system*).

Along the length of the pyramids, approximately 85% of the axons decussate to enter the descending **lateral corticospinal tracts** on the opposite side of the spinal cord. The other 15% continue uncrossed along the spinal cord as the **anterior corticospinal tracts**. Then, at the spinal segment it targets, an axon in the anterior corticospinal tract decussates in the anterior white commissure. The axon synapses on lower motor neurons in the anterior horns.

The Motor Homunculus

The activity of pyramidal cells in a specific portion of the primary motor cortex results in the contraction of specific peripheral muscles. Which muscles are stimulated depends on which region of motor cortex is active. As in the primary somatosensory cortex, the primary motor cortex corresponds point by point with specific regions of the body. The cortical areas have been mapped out in diagrammatic form, creating a **motor homunculus**. **Figure 15–11** shows the motor homunculus of the left cerebral hemisphere and the corticospinal pathway controlling skeletal muscles on the right side of the body.

The proportions of the motor homunculus are quite different from those of the actual body, because the area of primary motor cortex devoted to a specific body region is proportional to the density of motor units involved in the region's control, not to the region's physical size. For this reason, the homunculus

indicates the degree of fine motor control available. For example, the hands, face, and tongue are all capable of varied and complex movements, so they appear very large. In contrast, the trunk is relatively small. These proportions are similar to those of the sensory homunculus (**Spotlight Figure 15–8**).

The sensory and motor homunculi differ, however, with respect to some other areas of the body. For example, some highly sensitive regions, such as the sole of the foot, contain few motor units. Also, some areas with an abundance of motor units, such as the eye muscles, are not particularly sensitive.

Figure 15–11 The Corticospinal Pathway. The corticospinal pathway originates at the primary motor cortex. The corticobulbar tracts end at the motor nuclei of cranial nerves on the opposite side of the brain. Most fibers in this pathway cross over in the medulla oblongata and enter the lateral corticospinal tracts; the rest descend in the anterior corticospinal tracts and cross over after reaching target segments in the spinal cord.

The Medial and Lateral Pathways

Several centers in the cerebrum, diencephalon, and brainstem may issue somatic motor commands because of processing at a subconscious level. These centers and their associated tracts were long known as the *extrapyramidal system (EPS)* because they were thought to operate independently of, and in parallel with, the corticospinal pathway (pyramidal system). However, this classification scheme is both inaccurate and misleading because motor control is integrated at all levels through extensive feedback loops and interconnections. We now group these nuclei and tracts in terms of their *primary functions*: The components of the *medial pathway* help control gross movements of the trunk and proximal limb muscles, and those of the *lateral pathway* help control the distal limb muscles that perform more precise movements.

The medial and lateral pathways can modify or direct skeletal muscle contractions by stimulating, facilitating, or inhibiting lower motor neurons. Note that the axons of upper motor neurons in the medial and lateral pathways synapse on the same lower motor neurons innervated by the corticospinal pathway. This means that the various motor pathways interact not only within the brain, through connections between the primary motor cortex and motor centers in the brainstem, but also at the level of the lower motor neuron, through excitatory or inhibitory interactions.

The Medial Pathway

The **medial pathway** is primarily concerned with the control of muscle tone and gross movements of the neck, trunk, and proximal limb muscles. The upper motor neurons of the medial pathway are in the *vestibular nuclei*, the *superior* and *inferior colliculi*, and the *reticular formation*.

The vestibular nuclei (located at the border of the pons and medulla) receive information over the vestibulocochlear nerve (VIII). This nerve has receptors in the internal ear that monitor the position and movement of the head. These nuclei respond to changes in the orientation of the head, sending motor commands that alter the muscle tone, extension, and position of the neck, eyes, head, and limbs. The primary goal is to maintain posture and balance. The descending fibers in the spinal cord constitute the **vestibulospinal tracts** (Figure 15-10).

The superior and inferior colliculi are in the *tectum*, or roof of the midbrain. The superior colliculi receive visual sensations, and the inferior colliculi receive auditory sensations. Axons of upper motor neurons in the colliculi descend in the **tectospinal tracts**. These axons decussate immediately, before descending to synapse on lower motor neurons in the brainstem or spinal cord. Axons in the tectospinal tracts direct reflexive changes in the position of the head, neck, and upper limbs in response to bright lights, sudden movements, or loud noises.

The *reticular formation* is a loosely organized network of neurons that extends throughout the brainstem and has

Clinical Note Amyotrophic Lateral Sclerosis

Amyotrophic lateral sclerosis (ALS) is a progressive, degenerative disorder that affects motor neurons in the spinal cord, brainstem, and cerebral hemispheres. The degeneration affects both upper and lower motor neurons. A defect in axonal transport is thought to underlie the disease. Because a motor neuron and its dependent muscle fibers are so intimately related, the destruction of CNS neurons causes the associated skeletal muscles to atrophy. ALS is commonly known as Lou Gehrig's disease, named after the famous New York Yankees baseball player who died of the disorder.

extensive interconnections with the cerebrum, the cerebellum, and brainstem nuclei. Axons of upper motor neurons in the reticular formation of the pons and medulla oblongata descend into the **medial** (pontoreticulospinal) and **lateral** (medullary reticulospinal) **reticulospinal tracts** without crossing to the opposite side. The reticular formation receives input from almost every ascending and descending pathway. The region stimulated determines the effects of reticular formation stimulation. For example, the stimulation of upper motor neurons in one portion of the reticular formation produces eye movements. The stimulation of another portion activates respiratory muscles.

The Lateral Pathway

The **lateral pathway** is primarily concerned with the control of muscle tone and the more precise movements of the distal parts of the limbs. The upper motor neurons of the lateral pathway lie within the red nuclei of the midbrain. Axons of upper motor neurons in the red nuclei decussate in the brain and descend into the spinal cord in the **rubrospinal tracts** (*ruber*, red). In humans, the rubrospinal tracts are small and extend only to the cervical spinal cord. There they provide motor control over distal muscles of the upper limbs. Normally, their role is insignificant as compared with that of the lateral corticospinal tracts. However, the rubrospinal tracts can be important in maintaining motor control and muscle tone in the upper limbs if the lateral corticospinal tracts are damaged.

Table 15-2 summarizes the descending (motor) tracts discussed in this section.

The Monitoring Role of the Basal Nuclei and Cerebellum

The *basal nuclei* and *cerebellum* are responsible for coordination and feedback control over muscle contractions. Those contractions can be consciously or subconsciously directed.

Table 15–2 Descending (Motor) Pathways

Tract	Location of Upper Motor Neurons	Destination	Site of Decussation	Action
CORTICOSPINAL PATHWAY				
Corticobulbar tracts	Primary motor cortex (cerebral hemisphere)	Lower motor neurons of cranial nerve nuclei in brainstem	Brainstem	Conscious motor control of skeletal muscles
Lateral corticospinal tracts	Primary motor cortex (cerebral hemisphere)	Lower motor neurons of anterior horns of spinal cord	Pyramids of medulla oblongata	Conscious motor control of skeletal muscles
Anterior corticospinal tracts	Primary motor cortex (cerebral hemisphere)	Lower motor neurons of anterior horns of spinal cord	Level of lower motor neuron	Conscious motor control of skeletal muscles
MEDIAL PATHWAY				
Vestibulospinal tracts	Vestibular nuclei (at border of pons and medulla oblongata)	Lower motor neurons of anterior horns of spinal cord	None (uncrossed)	Subconscious regulation of balance and muscle tone
Tectospinal tracts	Tectum (midbrain: superior and inferior colliculi)	Lower motor neurons of anterior horns (cervical spinal cord only)	Brainstem (midbrain)	Subconscious regulation of eye, head, neck, and upper limb position in response to visual and auditory stimuli
Reticulospinal tracts	Reticular formation (network of nuclei in brainstem)	Lower motor neurons of anterior horns of spinal cord	None (uncrossed)	Subconscious regulation of reflex activity
LATERAL PATHWAY				
Rubrospinal tracts	Red nuclei of midbrain	Lower motor neurons of anterior horns of spinal cord	Brainstem (midbrain)	Subconscious regulation of upper limb muscle tone and movement

The Basal Nuclei and Patterns of Movement

The **basal nuclei** of the cerebrum provide the background patterns of movement involved in voluntary motor activities. For example, they may control muscles that determine the background position of the trunk or limbs, or they may direct rhythmic cycles of movement, as in walking or running. These nuclei do not exert direct control over lower motor neurons. Instead, they adjust the activities of upper motor neurons in the various motor pathways based on input from all portions of the cerebral cortex, as well as from the substantia nigra.

The basal nuclei adjust or establish patterns of movement by two major pathways:

- One group of axons synapses on thalamic neurons, whose axons extend to the *premotor cortex*, the motor association area that directs activities of the primary motor cortex. This arrangement creates a feedback loop that changes the sensitivity of the pyramidal cells and alters the pattern of instructions carried by the corticospinal tracts.
- A second group of axons synapses in the reticular formation, altering the excitatory or inhibitory output of the reticulospinal tracts.

Two distinct populations of interneurons exist in the basal nuclei: one that stimulates neurons by releasing acetylcholine (ACh), and another that inhibits neurons by releasing gamma aminobutyric acid (GABA). Under normal conditions, the excitatory interneurons are kept inactive, and the axons leaving the basal nuclei have an inhibitory effect on upper motor neurons. In *Parkinson's disease*, the excitatory neurons become more active, leading to problems with the voluntary control of movement.

If the primary motor cortex is damaged, the person loses fine motor control over skeletal muscles. However, the basal nuclei can still control some voluntary movements. In effect, the medial and lateral pathways function as they usually do, but the corticospinal pathway cannot fine-tune the movements. For example, after damage to the primary motor cortex, the basal nuclei can still receive information about planned movements from the prefrontal cortex and can perform preparatory movements of the trunk and limbs. But because the corticospinal pathway is inoperative, precise movements of the forearms, wrists, and hands cannot occur. An individual in this condition can stand, maintain balance, and even walk, but all movements are hesitant, awkward, and poorly controlled.

The Cerebellum and Movement Adjustments

Whenever movement is occurring, the cerebellum monitors proprioceptive (position) sensations, visual information from the eyes, and vestibular (balance) sensations from the internal ear. Axons within the spinocerebellar tracts deliver proprioceptive information to the cerebellar cortex. Visual information is relayed from the superior colliculi, and balance information is relayed from the vestibular nuclei. During this process the cerebellum is comparing the arriving sensations with those experienced during previous movements.

When motor commands are issued, all motor pathways also send information to the cerebellum. In general, any voluntary movement begins with the activation of far more motor units than are required. The cerebellum then acts like a brake, adjusting the activities of the upper motor neurons involved to inhibit the number of motor commands used for that movement. The output of the cerebellum affects upper motor neuron activity in

the corticospinal, medial, and lateral pathways. The pattern and degree of inhibition change from moment to moment, making the movement efficient, smooth, and precisely controlled.

The patterns of cerebellar activity are learned by trial and error, over many repetitions. Many of the basic patterns are established early in life. Examples include the fine balancing adjustments a person makes while standing and walking. The ability to fine-tune a complex pattern of movement improves with practice, until the movements become fluid and automatic. Consider the relaxed, smooth movements of acrobats, golfers, and sushi chefs. These people move without thinking about the details of their movements. Conversely, think about what happens when a person concentrates on voluntary control of various movements.

The rhythm and pattern of the movement usually fall apart as the primary motor cortex starts overriding the commands of the basal nuclei and cerebellum.

Checkpoint

11. What is the anatomical basis for the fact that the left side of the brain controls motor function on the right side of the body?
12. An injury involving the superior portion of the motor cortex affects which region of the body?
13. What effect would stimulation of the motor neurons of the red nucleus have on muscle tone?

See the blue Answers tab at the back of the book.

15 Chapter Review

Study Outline

An Introduction to Sensory Pathways and the Somatic Nervous System

1. The nervous system works as an integrated unit. This chapter considers sensory pathways (sensory receptors and sensory processing centers in the brain) and motor pathways (including both conscious and subconscious motor functions). (Figure 15-1)

15-1 Sensory stimuli cause signals to be sent along sensory pathways, and in response motor commands are sent along motor pathways

2. The brain, spinal cord, and peripheral nerves continuously communicate with each other and with the internal and external environments. Information arrives by sensory receptors and ascends within the afferent division, while motor commands descend and are distributed by the efferent division.

15-2 Sensory receptors connect our internal and external environments with the nervous system

3. A sensory receptor is a specialized cell or cell process that monitors specific conditions within the body or in the external environment. Arriving information is a **sensation**; awareness of a sensation is a **perception**.
4. The **general senses** are our sensitivity to temperature, pain, touch, pressure, vibration, and proprioception. Receptors for these senses are distributed throughout the body. **Special senses**, located in specific **sense organs**, are structurally more complex.
5. Each receptor cell monitors a specific *receptive field*. *Transduction* begins when a large enough stimulus depolarizes the *receptor potential* or *generator potential* to the point where action potentials are produced. (Figure 15-2)
6. A **labeled line** is a link between a peripheral receptor and a cortical neuron. **Tonic receptors** are always active. **Phasic receptors** provide information about the intensity and rate of change of a stimulus. **Adaptation** is a reduction in sensitivity in the presence of a constant stimulus. Phasic receptors

- PhysioEx

are **fast-adapting receptors**, while tonic receptors are **slow-adapting receptors**. (Figure 15-3)

15-3 General sensory receptors can be classified by the type of stimulus that excites them

7. Three types of **nociceptors** in the body provide information on pain as related to extremes of temperature, mechanical damage, and dissolved chemicals. Myelinated Type A fibers carry **fast pain**. Unmyelinated Type C fibers carry **slow pain**.
8. **Thermoreceptors** are found in the dermis. **Mechanoreceptors** are sensitive to distortion of their membranes, and include **tactile receptors**, **baroreceptors**, and **proprioceptors**. There are six types of tactile receptors in the skin and three kinds of proprioceptors. **Chemoreceptors** include **carotid bodies** and **aortic bodies**. (Figures 15-4 through 15-6)

15-4 The afferent division is made up of separate somatic sensory and visceral sensory pathways that deliver sensory information to the CNS

9. Sensory neurons that deliver sensation to the CNS are referred to as **first-order neurons**. These synapse on **second-order neurons** in the brainstem or spinal cord. The next neuron in this chain is a **third-order neuron**, found in the thalamus.
10. Three major somatic sensory pathways carry sensory information from the skin and musculature of the body wall, head, neck, and limbs: the *spinothalamic pathway*, the *posterior column pathway*, and the *spinocerebellar pathway*. (Figure 15-7)

11. The **spinothalamic pathway** carries poorly localized ("crude") sensations of touch, pressure, pain, and temperature. The axons involved decussate in the spinal cord and ascend within the **anterior** and **lateral spinothalamic tracts** to the ventral nuclei of the thalamus. Abnormalities along the spinothalamic pathway can lead to **phantom limb syndrome**, painful sensations that are perceived despite a missing limb, and **referred pain**, inaccurate localizations of the source of pain. (*Spotlight Figure 15–8, Figure 15–9; Table 15–1*)
 12. The **posterior column pathway** carries fine touch, pressure, and proprioceptive sensations. The axons ascend within the **gracile fasciculus** and **cuneate fasciculus** and relay information to the thalamus by the **medial lemniscus**. Before the axons enter the medial lemniscus, they cross over to the opposite side of the brainstem. This crossing over is called **decussation**. (*Spotlight Figure 15–8; Table 15–1*)
 13. The **spinocerebellar pathway**, including the **posterior** and **anterior spinocerebellar tracts**, carries sensations to the cerebellum concerning the position of muscles, tendons, and joints. (*Spotlight Figure 15–8; Table 15–1*)
 14. Visceral sensory pathways carry information collected by interoceptors. Sensory information from cranial nerves V, VII, IX, and X is delivered to the **solitary nucleus** in the medulla oblongata. Posterior roots of spinal nerves T_1-L_2 carry visceral sensory information from organs between the diaphragm and the pelvic cavity. Posterior roots of spinal nerves S_2-S_4 carry sensory information from more inferior structures.
- 15-5 The somatic nervous system is an efferent division made up of somatic motor pathways that control skeletal muscles**
15. Somatic motor (descending) pathways always involve an **upper motor neuron** (whose cell body lies in a CNS processing center) and a **lower motor neuron** (whose cell body is located in a nucleus of the brainstem or spinal cord). (*Figure 15–10*)
 16. The neurons of the primary motor cortex are *pyramidal cells*. The **corticospinal pathway** provides voluntary skeletal muscle control. The **corticobulbar tracts** end at the cranial nerve nuclei. The **corticospinal tracts** synapse on lower motor neurons in the anterior horns of the spinal cord. The corticospinal tracts are visible along the medulla oblongata as a pair of thick bands, the **pyramids**, where most of the axons decussate to enter the descending **lateral corticospinal tracts**. Those that do not cross over enter the **anterior corticospinal tracts**. The corticospinal pathway provides a rapid, direct mechanism for controlling skeletal muscles. (*Figure 15–11; Table 15–2*)
 17. The **medial** and **lateral pathways** include several other centers that issue motor commands because of processing performed at a subconscious level. (*Table 15–2*)
 18. The medial pathway primarily controls gross movements of the neck, trunk, and proximal limbs. It includes the vestibulospinal, tectospinal, and medial and lateral reticulospinal tracts. The **vestibulospinal tracts** carry information related to maintaining balance and posture. Commands carried by the **tectospinal tracts** change the position of the head, neck, and upper limbs in response to bright lights, sudden movements, or loud noises. Motor commands carried by the **reticulospinal tracts** vary according to the region stimulated. (*Table 15–2*)
 19. The lateral pathway consists of the **rubrospinal tracts**, which primarily control muscle tone and movements of the distal muscles of the upper limbs. (*Table 15–2*)
 20. The basal nuclei adjust the motor commands issued in other processing centers and provide background patterns of movement involved in voluntary motor activities.
 21. The cerebellum monitors proprioceptive sensations, visual information, and vestibular (balance) sensations. The integrative activities performed by neurons in the cortex and nuclei of the cerebellum are essential for the precise control of movements.

Review Questions

See the blue Answers tab at the back of the book.

LEVEL 1 Reviewing Facts and Terms

1. The larger the receptive field, the **(a)** larger the stimulus needed to stimulate a sensory receptor, **(b)** fewer sensory receptors there are, **(c)** harder it is to locate the exact point of stimulation, **(d)** larger the area of the somatosensory cortex in the brain that deals with the area, **(e)** closer together the receptor cells.
2. _____ receptors are always active and the rate of action potential generation changes according to the level of stimulation.
3. The CNS interprets information entirely based on the **(a)** number of action potentials that it receives, **(b)** kind of action potentials that it receives, **(c)** line over which sensory information arrives, **(d)** intensity of the sensory stimulus, **(e)** number of sensory receptors that are stimulated.
4. The area of primary somatosensory cortex devoted to a body region is relative to the **(a)** size of the body area, **(b)** distance of the body area from the brain, **(c)** density of motor units in the area of the body, **(d)** density of sensory receptors in the specific area of the body, **(e)** size of the nerves that serve the area of the body.
5. Identify and shade in the locations of all the ascending sensory tracts in the following diagram of the spinal cord.

6. Identify six types of tactile receptors located in the skin and describe their sensitivities.
7. What are the three major groups of proprioceptors?

562 UNIT 3 Control and Regulation

8. What are the three major somatic sensory pathways and their functions?
9. What is the function of the corticobulbar tracts?
10. What is the destination of the reticulospinal tracts?
11. What is the role of baroreceptors in the major vessels and in the lungs?
12. The basal nuclei **(a)** exert direct control over lower motor neurons, **(b)** direct rhythmic cycles of movement, as in walking or running, **(c)** monitor proprioceptive sensations, **(d)** do all of these.
13. Explain what is characteristic of slow-pain sensations.

LEVEL 2 Reviewing Concepts

14. Explain the difference between transduction and adaptation.
15. What is a motor homunculus? How does it differ from a sensory homunculus?
16. Describe the relationship among first-order, second-order, and third-order neurons in a sensory pathway.
17. Damage to the left side of the primary motor cortex in the region that controls the muscles of the arm and hand would interfere with the movement of which limb(s)?
18. What causes the degenerative disorder amyotrophic lateral sclerosis?

19. Do visceral organs have more or fewer sensory receptors than the skin? Why is the information coming from the visceral sensory receptors poorly localized?
20. Explain the phenomenon of *referred pain* in terms of labeled lines and organization of sensory tracts and pathways.

LEVEL 3 Critical Thinking and Clinical Applications

21. Eight-year-old Rosy's parents encourage her to learn to play the violin. This would require learning to master a series of complex movements. Rosy is told that mastering these movements at a young age is easier and that a lot of practice is essential. What role does the cerebellum have in helping Rosy obtain the skills she needs to become a good performer?
22. Harry, a construction worker, fractures his skull when a beam falls on his head. Diagnostic tests indicate severe damage to the primary motor cortex. His wife is anxious to know if he will ever be able to move or walk again. What explanation should the physician provide?
23. Victor is 55-years-old and diagnosed with Parkinson's disease. He moves slowly and even some simple movements are difficult for him. His muscles are often stiff and sometimes painful. He speaks in a monotone voice and cannot stop his hands from shaking. What is the source of Victor's problem?

15

**CLINICAL CASE Wrap-Up Living with Cerebral Palsy**

Communication between the periphery and the central nervous system follows neural pathways. Somatic sensory tracts are ascending, ending in the brain. Somatic motor tracts are descending, beginning in the brain. Between the input and the output, nerve impulses are analyzed, influenced, and modified in various parts of the brain, including the cerebrum, cerebellum, basal nuclei, hippocampus, and thalamus. These were the very areas of Michael's brain that were injured during birth.

The damage affected the sensory and motor processing centers in the brain. As a result, Michael's voluntary movements, muscle tone, postural muscle control, and balance were all affected. These deficits were stable and did not get worse. There was no limit to the development of the rest of Michael's brain or how brilliant he could become.

Despite his disabilities, Michael chose to define himself in terms of his abilities. He earned his Ph.D. in special education. He was a pioneer and became a catalyst in introducing the concept of self-determination to the field of education. He has been an educator, writer, and motivator his entire life.

1. Name the descending motor pathways that carry information that would be affected by the brain damage causing Michael's cerebral palsy.
2. Besides aspiration pneumonia, what other difficulties could result from poor motor control of the muscles used in swallowing?

See the blue Answers tab at the back of the book.

Related Clinical Terms

analgesia: The inability to feel pain while still conscious.

flaccid paralysis: Weakness or loss of muscle tone resulting from disease or injury to the nerves innervating the muscles.

hyperalgesia: Increased sensitivity to pain that may be caused by damage to nociceptors or peripheral nerves.

pain threshold: The lowest intensity of stimulation at which pain is experienced. It can vary among individuals.

pain tolerance: The maximum pain level an individual can withstand. It can vary among individuals.

spastic paralysis: The chronic pathological condition in which muscles are affected by persistent spasms and exaggerated tendon reflexes due to damage to motor nerves of the central nervous system.

syphilis: A sexually transmitted disease (STD), also called a sexually transmitted infection (STI), caused by the bacterium *Treponema pallidum*. Many of the signs and symptoms are indistinguishable from those of other diseases. Late-stage untreated syphilis can cause progressive degeneration of the posterior column pathway, spinocerebellar pathway, and posterior roots of the spinal cord.

The Autonomic Nervous System and Higher-Order Functions

Learning Outcomes

These Learning Outcomes correspond by number to this chapter's sections and indicate what you should be able to do after completing the chapter.

- 16-1 ■ Compare the organization of the autonomic nervous system with that of the somatic nervous system and name the divisions and major functions of the ANS.
- 16-2 ■ Describe the structures and functions of the sympathetic division of the autonomic nervous system.
- 16-3 ■ Describe the types of neurotransmitters and receptors and explain their mechanisms of action.
- 16-4 ■ Describe the structures and functions of the parasympathetic division of the autonomic nervous system.
- 16-5 ■ Describe the mechanisms of parasympathetic neurotransmitter release and their effects on target organs and tissues.
- 16-6 ■ Compare and contrast the sympathetic and parasympathetic nervous systems.
- 16-7 ■ Discuss the functional significance of dual innervation and autonomic tone.
- 16-8 ■ Describe the hierarchy of interacting levels of control in the autonomic nervous system, including the significance of visceral reflexes.
- 16-9 ■ Explain how memories are created, stored, and recalled; distinguish among the levels of consciousness and unconsciousness; and describe how neurotransmitters influence brain function.
- 16-10 ■ Summarize the effects of aging on the nervous system and give examples of interactions between the nervous system and other organ systems.

CLINICAL CASE

Remember Me?

It started with the little things. Mabella kept misplacing her keys. I'd try and get her to think, "When did you last have them?" Not knowing where her keys were upset her. She was always so organized when she was raising our four kids. She'd be fine for a while. Then she'd get turned around in the neighborhood grocery store. The day she turned 60, she forgot we were having her big birthday celebration. She was anxious; I was worried. We made an appointment with the doctor.

Our family doctor has known us for years. She listened carefully to Mabella and me and so was able to trace the start of the problem back to a year ago. Her physical exam turned out normal. Then Doc performed a little test. She told Mabella a list of three things and had her repeat them back. Later in the appointment, Doc asked

her again to repeat the items. Mabella was trying to concentrate, but she could only remember one item.

Well, it went downhill from there, slowly but steadily. Doc gave us a medication to try, and it helped for a while. I'm retired and I could do a lot for Mabella. We used the adult day care at the senior center so she would have something fun to do in the mornings and I could get a few errands done. Then Mabella needed more and more attention. She was restless. She didn't talk anymore. When our son moved

back home to help, she was afraid of him. This is hardest on Mabella, I guess, but it is hard on all of us, really. We've lost the Mabella we knew. **Why can't Mabella remember? To find out, turn to the Clinical Case Wrap-Up at the end of the chapter.**

16

An Introduction to the Autonomic Nervous System and Higher-Order Functions

In this chapter we focus on the *autonomic nervous system*, or *visceral motor system*, which adjusts our basic life support systems without our conscious control. We also consider aspects of higher-order functions such as consciousness, learning, and intelligence. Finally, we look at the effects of aging on the nervous system and conclude with an overview of interactions between the nervous system and other body systems.

16-1 The autonomic nervous system, which has sympathetic and parasympathetic divisions, is involved in the unconscious regulation of visceral functions

Learning Outcome Compare the organization of the autonomic nervous system with that of the somatic nervous system, and name the divisions and major functions of the ANS.

A person's conscious thoughts, plans, and actions are a tiny fraction of what the nervous system does. If all consciousness were eliminated, their vital physiological processes would continue virtually unchanged. After all, a night's sleep is not a life-threatening event. Longer, deeper states of unconsciousness are not necessarily more dangerous, if a person gets nourishment and other basic care. People with severe brain injuries can survive in a coma for decades.

How do people survive under these conditions? Their survival is possible because the **autonomic nervous system (ANS)**

makes routine homeostatic adjustments in physiological systems without instructions or interference from the conscious mind. By itself the ANS coordinates cardiovascular, respiratory, digestive, urinary, and reproductive functions. It also adjusts internal water, electrolyte, nutrient, and dissolved gas concentrations in body fluids.

Somatic or visceral sensory information can trigger *visceral reflexes* (responses to stimuli in visceral organs), and the ANS distributes the motor commands of those reflexes. Sometimes those motor commands control the activities of target organs. For example, in cold weather, the ANS stimulates the arrector pili muscles causing "goosebumps," small bumps that appear on the skin surface. In other cases, the motor commands may alter some ongoing activity. A sudden, loud noise can startle a person and make them jump, but thanks to the ANS, that sound can also increase heart rate dramatically and temporarily stop all digestive gland secretion. These changes in visceral activity take place in response to *neurotransmitters* released by neurons of the ANS. A specific neurotransmitter may stimulate or inhibit activity, depending on the response of specific plasma membrane receptors. The major types of receptors are considered in Section 16-3. Let's begin our study of the autonomic nervous system by comparing its organization with that of the somatic nervous system and then go on to look at the ANS divisions and their overall functions.

Comparison of the Somatic and Autonomic Nervous Systems

Figure 16-1 compares the functional organization of the somatic and autonomic nervous systems. Both are efferent divisions that carry motor commands. The *somatic nervous system* (SNS) allows for voluntary control of skeletal muscles, while the ANS

Figure 16–1 Comparison of the Functional Organizations of the Somatic and Autonomic Nervous Systems.

The somatic nervous system affects skeletal muscles. Name effectors of the autonomic nervous system.

is responsible for involuntary control of visceral effectors such as smooth muscle, glands, cardiac muscle, and adipocytes. The primary structural difference between the two is that in the SNS, motor neurons of the central nervous system (CNS) exert direct control over skeletal muscles (**Figure 16–1a**). In the ANS, by contrast, motor neurons of the CNS synapse on visceral motor neurons in autonomic ganglia (clusters of nerve cell bodies in the ANS), and these ganglionic neurons control visceral effectors (**Figure 16–1b**).

Organization of the ANS

The hypothalamus contains the integrative centers for autonomic activity. The neurons in these centers are comparable to the upper motor neurons in the SNS. Visceral motor neurons in the brainstem and spinal cord are known as **preganglionic neurons** because they extend to ganglia. These neurons are part of *visceral reflex arcs*. Most of their activities represent direct reflex responses, rather than responses to commands from the

hypothalamus. The axons of preganglionic neurons are called **preganglionic fibers**.

Preganglionic fibers leave the CNS and synapse on **ganglionic neurons**, or **postganglionic neurons**—visceral motor neurons in peripheral ganglia. These ganglia, which contain hundreds to thousands of ganglionic neurons, are called **autonomic ganglia**. Ganglionic neurons innervate visceral effectors such as smooth muscle, glands, cardiac muscle, and adipocytes. The axons of ganglionic neurons are called **postganglionic fibers** because they begin at the autonomic ganglia and extend to the peripheral target organs.

Tips

Each autonomic ganglion functions somewhat like a baton handoff zone in a relay race. Within the ganglion, one runner (the preganglionic fiber) hands off the baton (a neurotransmitter) to the next runner (the postganglionic fiber), who then continues toward the finish line (the target effector).

Divisions of the ANS

In Chapter 12 we introduced two main subdivisions of the ANS: the **sympathetic division** and the **parasympathetic division**. The two divisions work both separately and together:

- Most often, these two divisions have opposing effects. For example, if the sympathetic division causes excitation in an effector, the parasympathetic causes inhibition in that same effector.
- The two divisions may also work independently. Only one division innervates some structures.
- The two divisions may work together, with each controlling one stage of a complex process.

In general, the sympathetic division “kicks in” only during exertion, stress, or emergency, and the parasympathetic division predominates under resting conditions. Let’s delve into the overall functions of these divisions.

16

The Sympathetic Division

An increase in sympathetic activity, called the “fight or flight” response, prepares the body to deal with emergencies. Imagine a person walking down a long, dark alley and hearing strange noises in the darkness ahead. Their body responds right away, and they become more alert and aware of their surroundings. Their metabolic rate increases quickly, up to twice its resting level. Digestive and urinary processes stop temporarily, and more blood flows to their skeletal muscles. Breathing becomes quicker and deeper. Both heart rate and blood pressure increase, circulating blood more rapidly. Their body warms and begins to perspire. We can summarize this general pattern of responses to an increased level of sympathetic activity as follows: (1) heightened mental alertness, (2) increased metabolic rate, (3) decreased digestive and urinary functions, (4) activation of energy reserves, (5) increased respiratory rate and dilation of respiratory passageways, (6) increased heart rate and blood pressure, and (7) activation of sweat glands.

The Parasympathetic Division

The parasympathetic division stimulates visceral activity. For example, it causes the state of “rest and digest” after eating a big dinner. After eating, the body relaxes, energy demands are minimal, and both heart rate and blood pressure are relatively low. Meanwhile, digestive organs are highly stimulated. The overall pattern of responses to increased parasympathetic activity is as follows: (1) decreased metabolic rate, (2) decreased heart rate and blood pressure, (3) increased secretion by salivary and digestive glands, (4) increased motility and blood flow in the digestive tract, and (5) stimulation of urination and defecation.

In this chapter, we focus primarily on the sympathetic and parasympathetic divisions, which integrate and coordinate

visceral functions throughout the body. We consider the enteric nervous system in Section 16-8, when we discuss visceral reflexes, and again when we examine the control of digestion in Chapter 24.

Checkpoint

1. Identify the two major divisions of the ANS.
2. How many motor neurons are needed to carry an action potential from the spinal cord to smooth muscles in the wall of the intestine?
3. While out for a walk, Julie suddenly meets an angry dog. Which division of the ANS is responsible for the physiological changes that occur in Julie as she turns and runs?

See the blue Answers tab at the back of the book.

16-2 The sympathetic division has short preganglionic fibers and long postganglionic fibers and is involved in using energy and increasing metabolic rate

Learning Outcome Describe the structures and functions of the sympathetic division of the autonomic nervous system.

Spotlight Figure 16-2a presents the overall organization of the sympathetic division of the ANS, which is responsible for mobilizing the body’s energy and resources to respond to stressful situations. This division consists of the following:

- *Short Preganglionic Fibers in Thoracic and Lumbar Segments of the Spinal Cord.* This division is also called the *thoracolumbar division* because its preganglionic neurons are located between segments T₁ and L₂ of the spinal cord. The cell bodies of the preganglionic neurons are within the lateral horns, and their axons enter the anterior roots of these segments.
- *Ganglionic Neurons in Ganglia near the Spinal Cord.* The preganglionic fibers are relatively short because the ganglia are located near the spinal cord. They release acetylcholine (ACh), stimulating ganglionic neurons.
- *Long Postganglionic Fibers to Target Organs.* The postganglionic fibers are relatively long. (An exception occurs at the adrenal medullae, which is discussed later in this section.)

Functional Organization of the Sympathetic Division

Spotlight Figure 16-2a provides a detailed view of the sympathetic division. The left side of the figure shows the somatic distribution to the skin, skeletal muscles, and other tissues of the body wall. The right side shows the innervation of visceral organs.

Sympathetic preganglionic fibers originate from the lateral horns and become part of the spinal anterior roots. We described the basic pattern of sympathetic innervation in these regions in **Spotlight Figure 13–8**. After passing through the intervertebral foramen, each anterior root gives rise to a myelinated white ramus communicans (plural, *rami communicantes*), which carries myelinated preganglionic fibers into a nearby *sympathetic chain ganglion* found on either side of the vertebral column. These fibers diverge extensively, with one preganglionic fiber synapsing on two dozen or more ganglionic neurons. Preganglionic fibers running between the sympathetic chain ganglia interconnect them, making the chain look like a string of pearls. Each sympathetic chain ganglion innervates a particular body organ or group of organs.

Where ganglionic neurons synapse, or which pathway they follow, determines which target organs they will affect. These neurons may synapse in three locations: within the sympathetic chain ganglia, and/or at one of the collateral ganglia, or in the adrenal medullae (**Figure 16–3**).

- **Sympathetic Chain Ganglia.** **Sympathetic chain ganglia**, also called *paravertebral ganglia*, lie on each side of the vertebral column (**Figure 16–3a**). Neurons in these ganglia control effectors in the body wall, thoracic cavity, head, neck, and limbs.
- **Collateral Ganglia.** **Collateral ganglia**, also known as *prevertebral ganglia*, are anterior to the vertebral column (**Figure 16–3b**). Collateral ganglia contain ganglionic neurons that innervate abdominopelvic tissues and viscera.
- **Adrenal Medullae.** The center of each adrenal (*ad-*, near + *renal*, kidney) gland, the **adrenal medulla**, is a modified sympathetic ganglion (**Figure 16–3c**). The ganglionic neurons of the adrenal medullae have very short axons. When these medullary cells are stimulated, they secrete neurotransmitters directly into the bloodstream, not at a synapse. This mode of release allows the neurotransmitters to function as *hormones*, affecting target cells throughout the body.

Sympathetic Chain Ganglia Pathway: Upper Body

If a preganglionic fiber carries motor commands targeting structures in the body wall, thoracic cavity, head, neck, or limbs, it synapses in one or more sympathetic chain ganglia. Each sympathetic chain contains 3 cervical, 10–12 thoracic, 4–5 lumbar, and 4–5 sacral ganglia, plus 1 coccygeal ganglion. (The numbers vary because adjacent ganglia sometimes fuse.) Preganglionic neurons are limited to spinal cord segments T_1 – L_2 , and these spinal nerves have both *white rami communicantes* (myelinated preganglionic fibers) and *gray rami communicantes* (unmyelinated postganglionic fibers). The neurons in the cervical, inferior lumbar, and sacral sympathetic chain

ganglia are innervated by preganglionic fibers that run along the axis of the chain. In turn, these chain ganglia provide postganglionic fibers, through gray rami communicantes, to the cervical, lumbar, and sacral spinal nerves. As a result, only spinal nerves T_1 – L_2 have white rami communicantes, and every spinal nerve has a gray ramus communicans that carries sympathetic postganglionic fibers for distribution in the body wall.

The unmyelinated postganglionic fibers then follow one of two different paths, depending on where their targets lie:

- Postganglionic fibers that control visceral effectors in the body wall, head, neck, or limbs enter the gray ramus communicans and return to the spinal nerve for subsequent distribution (**Figure 16–3a**). These postganglionic fibers innervate sweat glands, smooth muscles in superficial blood vessels, and arrector pili muscles in the skin (**Spotlight Figure 16–2a**).
- Postganglionic fibers innervating visceral organs in the thoracic cavity, such as the heart and lungs, form bundles known as **sympathetic nerves** (**Figure 16–3a**).

For the sake of clarity, **Figure 16–3a** shows sympathetic nerves on the left side and spinal nerve distribution on the right, but both innervation patterns occur on *each* side of the body.

The spinal nerves provide somatic motor innervation to skeletal muscles of the body wall and limbs, but they also distribute sympathetic postganglionic fibers (**Figure 16–3a** and **Spotlight Figure 16–2a**). About 8% of the axons in each spinal nerve are sympathetic postganglionic fibers. In the head and neck, sympathetic postganglionic fibers leaving the superior cervical sympathetic ganglia supply the regions and structures innervated by cranial nerves III, VII, IX, and X.

In summary:

- The cervical, inferior lumbar, and sacral chain ganglia receive preganglionic fibers from spinal segments T_1 – L_2 .
- Only the thoracic and superior lumbar ganglia (T_1 – L_2) receive preganglionic fibers from white rami communicantes.
- Every spinal nerve receives a gray ramus communicans from a ganglion of the sympathetic chain.

Collateral Ganglia Pathway: Abdominopelvic Cavity

The abdominopelvic viscera receive sympathetic innervation by sympathetic preganglionic fibers that synapse in separate collateral ganglia (**Figure 16–3b**). These fibers pass through the sympathetic chain without synapsing. They form the *splanchnic* (SPLANK-nik) *nerves*, which lie in the posterior wall of the abdominal cavity. In adults the collateral ganglia are typically single rather than paired. They originate as paired ganglia (left and right), but the two usually fuse.

AUTONOMIC NERVOUS SYSTEM

Consists of two divisions

a Sympathetic Division (Thoracolumbar Division)

b Parasympathetic Division (Craniosacral Division)

Figure 16–3 Sites of Ganglia in Sympathetic Pathways. Inferior views of sections through the thoracic spinal cord, showing the three major patterns of distribution for preganglionic and postganglionic fibers.

Postganglionic fibers leaving the collateral ganglia extend throughout the abdominopelvic cavity, innervating a variety of visceral tissues and organs. Their general function is to (1) reduce blood flow and energy use by organs that are not important to immediate survival (such as the digestive tract) and (2) release stored energy.

The preganglionic **splanchnic nerves** innervate three collateral ganglia. Preganglionic fibers from the seven inferior thoracic spinal segments end at either the *celiac* (SĒ-lĒ-ak) *ganglion* or the *superior mesenteric ganglion* (**Spotlight Figure 16–2a**). Preganglionic fibers from the lumbar segments form splanchnic nerves that end at the *inferior mesenteric ganglion*. All three ganglia are named after nearby arteries:

- The **celiac ganglion** is named after the *celiac trunk*, a major artery and its branches supplying the stomach, spleen, and liver. The celiac ganglion commonly consists of a pair of interconnected masses of gray matter located at the base of that artery. The celiac ganglion may also form a single mass or many small, interwoven masses. Postganglionic fibers from this ganglion innervate the stomach, liver, gallbladder, pancreas, and spleen.
- The **superior mesenteric ganglion** is found near the base of the *superior mesenteric artery*, which provides blood to the stomach, small intestine, and pancreas. Postganglionic fibers leaving the superior mesenteric ganglion innervate the small intestine and the proximal two-thirds of the large intestine.
- The **inferior mesenteric ganglion** is located near the base of the *inferior mesenteric artery*, which supplies the large intestine and other organs in the inferior portion of the abdominopelvic cavity. Postganglionic fibers from this ganglion provide sympathetic innervation to the kidneys, urinary bladder, terminal segments of the large intestine, and the sex organs.

Adrenal Medulla Pathway: Metabolic Effects

Preganglionic fibers entering an adrenal gland proceed to the central **adrenal medulla** (**Figure 16–3c** and **Spotlight Figure 16–2a**). In this modified sympathetic ganglion, preganglionic fibers synapse on secretory cells that secrete the neurotransmitters *epinephrine* (or *adrenaline*) and *norepinephrine* (or *noradrenaline*). Epinephrine makes up 75–80% of the secretory output; the rest is norepinephrine.

Which type of ganglionic neuron innervates visceral organs in the abdominopelvic cavity?

The bloodstream carries the neurotransmitters throughout the body, where they cause changes in the metabolic activities of many different cells. These effects resemble those produced by the stimulation of sympathetic postganglionic fibers. They differ, however, in two respects: (1) Cells not innervated by sympathetic postganglionic fibers are affected, and (2) the effects last much longer than those produced by direct sympathetic innervation, because the chemicals continue to diffuse out of the bloodstream for an extended period.

Sympathetic Activation

The sympathetic division can change the activities of tissues and organs by releasing norepinephrine at peripheral synapses, and by distributing epinephrine and norepinephrine throughout the body in the bloodstream. The visceral motor fibers that target specific effectors, such as smooth muscle fibers in blood vessels of the skin, can be activated in reflexes that do not involve other visceral effectors.

In a crisis, however, the entire division responds. This event, called **sympathetic activation**, is controlled by sympathetic centers in the hypothalamus. The effects are not limited to peripheral tissues, because sympathetic activation also alters CNS activity. When sympathetic activation occurs, a person experiences the following changes:

- Increased alertness by stimulation of the reticular activating system, causing the individual to feel “on edge.”
- A feeling of energy and euphoria, often associated with a disregard for danger and a temporary insensitivity to painful stimuli.
- Increased activity in the cardiovascular and respiratory centers of the pons and medulla oblongata, which increases blood pressure, heart rate, breathing rate, and depth of respiration.
- A general elevation in muscle tone through stimulation of the medial and lateral pathways, so the person *looks* tense and may begin to shiver.
- The mobilization of energy reserves, through the accelerated breakdown of glycogen in muscle and liver cells and the release of lipids by adipose tissues.

These changes, plus the peripheral changes already noted, prepare the person to cope with a stressful situation.

Checkpoint

4. Describe the positions of the sympathetic chain ganglia and collateral ganglia relative to the vertebral column.
5. Where do the nerves that synapse in collateral ganglia originate?

16-3 Different types of neurotransmitters and receptors lead to different sympathetic effects

Learning Outcome Describe the types of neurotransmitters and receptors and explain their mechanisms of action.

We have examined the structure of the sympathetic division of the ANS and the general effects of sympathetic activation. Now let's consider the cellular basis of these effects on peripheral organs.

When stimulated, sympathetic preganglionic neurons release *acetylcholine* (ACh) at synapses with ganglionic neurons. Synapses that use ACh as a transmitter are called *cholinergic*. The effect on the ganglionic neurons is always excitatory.

These ganglionic neurons then release neurotransmitters at specific target organs. The axon terminals differ from those at neuromuscular (nerve to muscle cell) junctions of the somatic nervous system. In the sympathetic nervous system, the axonal telodendria form a branching network, with each branch resembling a string of pearls. Each “pearl” is a swollen segment called a **varicosity** that is packed with neurotransmitter vesicles (**Figure 16-4**). Chains of varicosities are found along or near the surfaces of effector cells such as smooth muscle cells. These cells have no specialized postsynaptic membranes, such as the motor end plates in skeletal muscle cells. Instead, membrane receptors are scattered across the surfaces of the target cells.

Most sympathetic ganglionic neurons release norepinephrine (NE) at their varicosities. Neurons that release NE are called *adrenergic*. A small but significant number of ganglionic neurons in the sympathetic division release ACh rather than NE. Varicosities releasing ACh are in the body wall, the skin, the brain, and skeletal muscles.

The NE released by varicosities affects its targets until it is reabsorbed or inactivated by enzymes. Fifty to eighty percent of the NE is reabsorbed by varicosities and is either reused or broken down by the enzyme *monoamine oxidase* (MAO). The rest of the NE diffuses out of the area or is broken down by the enzyme *catechol-O-methyltransferase* (COMT) in surrounding tissues.

In general, the effects of NE on the postsynaptic membrane last for a few seconds, significantly longer than the 20-msec duration of ACh effects. (As usual, the responses of the target cells vary with the nature of their receptors.) When the adrenal medullae release NE and epinephrine (E) into the bloodstream, the effects last even longer because (1) the bloodstream does not contain MAO or COMT, and (2) most tissues contain relatively low concentrations of those enzymes. After the adrenal medullae are stimulated, tissue concentrations of NE and E throughout the body may remain elevated for as long as 30 seconds, and the effects may persist for several minutes. Let's focus on the receptors that these neurotransmitters stimulate and the effects of such stimulation.

Figure 16–4 Sympathetic Varicosities.

What neurotransmitter is released from most varicosities in the sympathetic division?

Effects of Sympathetic Stimulation of Adrenergic Synapses and Receptors

The effects of sympathetic stimulation result primarily from the interactions of NE and E with adrenergic membrane receptors. There are two classes of these receptors: *alpha receptors* and *beta receptors*. In general, NE stimulates alpha receptors to a greater degree than it does beta receptors, and E stimulates both classes of receptors. For this reason, localized sympathetic activity, involving the release of NE at varicosities, primarily affects nearby alpha receptors. By contrast, generalized sympathetic activation and the release of E by the adrenal medullae affect both alpha and beta receptors throughout the body.

Alpha receptors and beta receptors are *G protein-coupled receptors*. As we saw in Chapter 12, the effects of stimulating such a receptor depend on the production of *second messengers*, intracellular intermediaries with varied functions.

Alpha Receptors

Stimulation of **alpha (α) receptors** activates their associated G proteins on the cytoplasmic surface of the plasma membrane. There are two types of alpha receptors: *alpha-1* (α_1) and *alpha-2* (α_2).

- Alpha-1 receptors, the more common type of alpha receptor, are found primarily in smooth muscle cells of many different organs. The stimulation of this receptor results in G protein activation that brings about the release of intracellular calcium ions into the cytosol from reserves in the endoplasmic reticulum. This action generally has an excitatory effect on the target cell. For example, the stimulation of α_1 receptors on smooth muscle cells causes peripheral blood vessels to constrict and sphincters along the digestive tract and urinary bladder to close.
- Alpha-2 receptors are found on either preganglionic or postganglionic sympathetic neurons. Stimulation of α_2 receptors and G protein activation result in a lowering of the cyclic-AMP (cAMP) level in the cytoplasm. Cyclic-AMP is an important second messenger that can activate or inactivate key enzymes. This decrease generally has an inhibitory effect on the target cell. The presence of α_2 receptors in the parasympathetic division helps coordinate sympathetic and parasympathetic activities. When the sympathetic division is active, the NE released binds to α_2 receptors at parasympathetic neuromuscular and neuroglandular junctions and inhibits their activity.

Beta Receptors

Beta (β) receptors are located on the plasma membranes of cells in many organs, including skeletal muscles, the lungs, the heart, and the liver. The stimulation of beta receptors and G protein activation trigger changes in the metabolic activity of the target cell. These changes occur indirectly, as G protein activation results in an increase in intracellular cAMP levels. There are three major types of beta receptors: *beta-1* (β_1), *beta-2* (β_2), and *beta-3* (β_3).

- Stimulation of β_1 receptors increases metabolic activity. For example, stimulation of β_1 receptors in skeletal muscles accelerates the metabolic activities of the muscles. Stimulation of β_1 receptors in the heart increases heart rate and force of contraction.
- Stimulation of β_2 receptors causes inhibition, triggering the relaxation of smooth muscles along the respiratory tract. As a result, respiratory passageways dilate, making breathing easier. Inhalers used to treat asthma trigger this response.
- The β_3 receptor is found in adipose tissue. Stimulation of β_3 receptors causes *lipolysis*, the breakdown of triglycerides stored within adipocytes. Fatty acids generated through lipolysis are released into the bloodstream for use by other tissues.

Effects of Sympathetic Stimulation on Other Types of Synapses

Most sympathetic postganglionic fibers are adrenergic (release NE), but as we noted, a few are cholinergic (release ACh). Sympathetic postganglionic fibers innervate skin sweat glands and the blood vessels to skeletal muscles and the brain. The activation of these sympathetic fibers stimulates sweat gland secretion and dilates the blood vessels.

In some areas of the body, the sympathetic division requires the use of two types of synapses. For example, in the body wall and skeletal muscles, both ACh and NE are needed to regulate visceral functions with precision. ACh causes most small peripheral arteries to dilate (*vasodilation*), and NE causes them to constrict (*vasoconstriction*). This means that the sympathetic division can increase blood flow to skeletal muscles by releasing ACh to activate cholinergic synapses. At the same time, it can reduce the blood flow to other tissues in the body wall, by releasing NE to stimulate adrenergic synapses.

The sympathetic division also includes *nitroxidergic synapses*, which release *nitric oxide (NO)* as a neurotransmitter. Such synapses occur where neurons innervate smooth muscles in the walls of blood vessels in many regions, notably in skeletal muscles and the brain. The activity of these synapses produces vasodilation and increased blood flow through these regions.

Checkpoint

6. How would a drug that stimulates cholinergic receptors affect the sympathetic nervous system?
7. A person with high blood pressure is given a medication that blocks beta receptors. How could this medication help correct that person's condition?

See the blue Answers tab at the back of the book.

16-4 The parasympathetic division has long preganglionic fibers and short postganglionic fibers and is involved in conserving energy and lowering metabolic rate

Learning Outcome Describe the structures and functions of the parasympathetic division of the autonomic nervous system.

The parasympathetic division of the ANS is responsible for conserving the body's energy and maintaining the resting metabolic rate. Structurally, this division (**Spotlight Figure 16-2b**) consists of the following:

- *Long Preganglionic Fibers in the Brainstem and in Sacral Segments of the Spinal Cord.* All parts of the brainstem, the midbrain, pons, and medulla oblongata, contain autonomic nuclei associated with several cranial nerves. In sacral segments of

the spinal cord, the parasympathetic nuclei lie in the lateral horns of spinal segments S_2-S_4 . This divided pattern of neuron locations explains why the parasympathetic division is also called the *craniosacral division*.

- *Ganglionic Neurons in Peripheral Ganglia within or Adjacent to Target Organs.* Preganglionic fibers of the parasympathetic division do not diverge as extensively as do those of the sympathetic division. A typical preganglionic fiber synapses on six to eight ganglionic neurons, all in the same ganglion. The ganglion may be a **terminal ganglion**, located near the target organ, or an **intramural** (*muris*, wall) **ganglion**, embedded in the tissues of the target organ. Terminal ganglia are usually paired. Intramural ganglia typically consist of interconnected masses and clusters of ganglion cells.
- *Short Postganglionic Fibers in or near Target Organs.* The postganglionic fibers then extend from the terminal or intramural ganglion to the target organ. Having the ganglia and postganglionic neurons near the target organs makes the effects of parasympathetic stimulation very specific and localized.

Next, let's examine the functional organization and activation of the parasympathetic division.

Functional Organization of the Parasympathetic Division

Parasympathetic fibers innervate organs of three main regions: the cranial, trunk, and pelvic regions.

Parasympathetic preganglionic fibers leave the brain in cranial nerves III (oculomotor), VII (facial), IX (glossopharyngeal), and X (vagus) (**Spotlight Figure 16-2b**). These fibers carry the cranial parasympathetic output to visceral structures in the head. These fibers synapse in the *ciliary*, *pterygopalatine*, *submandibular*, and *otic ganglia*. Short postganglionic fibers continue to their peripheral targets.

The vagus nerve alone provides about 75% of all parasympathetic outflow (output from nerves leaving the CNS). It supplies preganglionic parasympathetic innervation to structures in the neck and in the thoracic and abdominopelvic cavities as distant as the distal portion of the large intestine. The many branches of the vagus nerve mingle with preganglionic and postganglionic fibers of the sympathetic division, forming plexuses comparable to those formed by spinal nerves innervating the limbs. (We consider these plexuses in Section 16-7.)

The preganglionic fibers in the sacral segments of the spinal cord carry the sacral parasympathetic output. These fibers do not join the anterior roots of the spinal nerves. Instead, they form distinct **pelvic nerves**, which innervate intramural ganglia in the walls of the kidneys, urinary bladder, terminal portions of the large intestine, and sex organs.

Parasympathetic Activation

The functions of the parasympathetic division center on relaxation, food processing, and nutrient absorption. This division has been called the *anabolic system* (*anabole*, a raising up), because its stimulation leads to a general increase in the nutrient content of the blood. In response to this increase, cells throughout the body absorb nutrients and use them to support growth and cell division and to create energy reserves in the form of lipids or glycogen.

The major effects of the parasympathetic division include the following:

- Constriction of the pupils (to limit the amount of light that enters the eyes) and focusing of the lenses of the eyes on nearby objects.
- Secretion by digestive glands, including salivary glands, gastric glands, duodenal glands, intestinal glands, the pancreas (exocrine and endocrine), and the liver.
- The secretion of hormones that promote the absorption and use of nutrients by peripheral cells.
- Changes in blood flow and glandular activity associated with sexual arousal.
- An increase in smooth muscle activity along the digestive tract.
- The stimulation and coordination of defecation.
- Contraction of the urinary bladder during urination.
- Constriction of the respiratory passageways.
- A reduction in heart rate and force of contraction.

✓ Checkpoint

8. Which nerve is responsible for the parasympathetic innervation of the lungs, heart, stomach, liver, pancreas, and parts of the small and large intestines?
9. Why is the parasympathetic division sometimes referred to as the anabolic system?

See the blue Answers tab at the back of the book.

16-5 Different types of receptors lead to different parasympathetic effects

Learning Outcome Describe the mechanisms of parasympathetic neurotransmitter release and their effects on target organs and tissues.

All parasympathetic neurons release ACh as a neurotransmitter. The effects on the postsynaptic cell can vary widely, however, due to different types of receptors or to the nature of the second messenger involved.

Effects of Parasympathetic Stimulation of Cholinergic Receptors

When parasympathetic neurons release ACh, the neurotransmitter may affect neurons, muscle fibers, or effector cells. The effects of stimulation are both localized and short lived. Most

of the ACh released is inactivated at the synapse by the enzyme *acetylcholinesterase* (AChE). Any ACh diffusing into the surrounding tissues is inactivated by the enzyme *tissue cholinesterase*.

The effects of ACh release depend to a large degree on what type of cholinergic receptor is stimulated. Two types of cholinergic receptors occur on the postsynaptic membranes: *nicotinic* and *muscarinic*.

Nicotinic Receptors

Nicotinic (nik-ō-TIN-ik) **receptors** occur on ganglion cells of both the parasympathetic and sympathetic divisions. (They also occur at neuromuscular junctions of the somatic nervous system.) When ACh activates nicotinic receptors, it opens chemically gated Na⁺ channels in the postsynaptic membrane of the ganglionic neuron or motor end plate of the muscle fiber, which always causes excitation of that cell.

Muscarinic Receptors

Muscarinic (mus-kuh-RIN-ik) **receptors** occur at cholinergic neuromuscular or neuroglandular junctions in the parasympathetic division. They also occur at the few cholinergic junctions in the sympathetic division. Muscarinic receptors are G protein-coupled receptors. Their stimulation and G protein activation produce longer-lasting effects than does the stimulation of nicotinic receptors. The response can be excitatory or inhibitory, depending on the activation or inactivation of specific enzymes.

Effects of Toxins on Cholinergic Receptors

The names *nicotinic* and *muscarinic* originated with researchers who found that dangerous environmental toxins bind to these receptor sites. Nicotinic receptors bind *nicotine*, a powerful toxin obtained from a variety of sources, including tobacco leaves. Muscarinic receptors are stimulated by *muscarine*, a toxin produced by some poisonous mushrooms.

These toxins have separate actions. Nicotine targets the autonomic ganglia and skeletal neuromuscular junctions. Muscarine acts at the parasympathetic neuromuscular or neuroglandular junctions. They produce dangerously exaggerated, uncontrolled responses due to abnormal stimulation of cholinergic or adrenergic receptors.

Nicotine poisoning occurs if as little as 50 mg of the compound is ingested or absorbed through the skin. (The highest nicotine level in tobacco is about 3 mg per gram.) The signs reflect widespread autonomic activation. They include vomiting, diarrhea, high blood pressure, rapid heart rate, sweating, and profuse salivation. Convulsions may occur because the neuromuscular junctions of the somatic nervous system are also stimulated. In severe cases, the stimulation of nicotinic receptors inside the CNS can lead to coma and death within minutes.

The signs and symptoms of muscarine poisoning are almost entirely restricted to the parasympathetic division. They include salivation, nausea, vomiting, diarrhea, constriction

Table 16–1 Adrenergic and Cholinergic Receptors of the ANS

Receptor	Location	Response	Mechanism
ADRENERGIC			
α_1	Widespread, found in most tissues	Excitation, stimulation of metabolism	Enzyme activation; intracellular release of Ca^{2+}
α_2	Sympathetic neuromuscular or neuroglandular junctions	Inhibition of effector cell	Reduction of cAMP concentration
α_2	Parasympathetic neuromuscular or neuroglandular junctions	Inhibition of neurotransmitter release	Reduction of cAMP concentration
β_1	Heart, kidneys, liver, adipose tissue*	Stimulation, increased energy consumption	Enzyme activation
β_2	Smooth muscle in vessels of heart and skeletal muscle; smooth muscle layers in intestines, lungs, bronchi	Inhibition, relaxation	Enzyme activation
CHOLINERGIC			
Nicotinic	All autonomic synapses between preganglionic and ganglionic neurons; neuromuscular junctions of SNS	Stimulation, excitation; muscular contraction	Opening of chemically gated Na^+ channels
Muscarinic	All parasympathetic and cholinergic sympathetic neuromuscular or neuroglandular junctions	Variable	Enzyme activation causing changes in membrane permeability to K^+

*Adipocytes also contain an additional receptor type, β_3 , not found in other tissues. Stimulation of β_3 receptors causes lipolysis.

of respiratory passages, low blood pressure, and an abnormally slow heart rate (bradycardia). Sweating, a sympathetic response, is also prominent. For this reason, *Amanita muscaria*, commonly known as the fly-agaric mushroom, is used in very small amounts in some Native American sweat lodge rituals.

Table 16–1 summarizes details about the adrenergic and cholinergic receptors of the ANS.

division has widespread impact, reaching organs and tissues throughout the body. The parasympathetic division innervates only visceral structures that are supplied by the cranial nerves or that lie within the abdominopelvic cavity.

✓ Checkpoint

- What neurotransmitter is released by all parasympathetic neurons?
- Name the two types of cholinergic receptors on the postsynaptic membranes of parasympathetic neurons.
- How would the stimulation of muscarinic receptors in cardiac muscle affect the heart?

See the blue Answers tab at the back of the book.

16-6 The differences in the organization of sympathetic and parasympathetic structures lead to widespread sympathetic effects and specific parasympathetic effects

Learning Outcome Compare and contrast the sympathetic and parasympathetic nervous systems.

Figure 16–5 and Table 16–2 compare key structural features of the sympathetic and parasympathetic divisions of the ANS. The differences in structure lead to differences in functions. The sympathetic

Figure 16–5 A Summary Comparison of the Sympathetic and Parasympathetic Divisions.

Table 16–2 A Structural Comparison of the Sympathetic and Parasympathetic Divisions of the ANS

Characteristic	Sympathetic Division	Parasympathetic Division
Location of CNS visceral motor neurons	Lateral horns of spinal segments T ₁ –L ₂	Brainstem and spinal segments S ₂ –S ₄
Location of PNS ganglia	Near vertebral column	Typically intramural
Preganglionic fibers (axons)		
Length	Relatively short	Relatively long
Neurotransmitter released	Acetylcholine	Acetylcholine
Postganglionic fibers (axons)		
Length	Relatively long	Relatively short
Neurotransmitter released	Normally NE; sometimes NO or ACh	Acetylcholine
Neuromuscular or neuroglandular junction	Varicosities and enlarged axonic terminals that release transmitter near target cells	Junctions that release transmitter to special receptor surface
Degree of divergence from CNS to ganglion cells	Approximately 1:32	Approximately 1:6
General function	Stimulates metabolism; increases alertness; prepares for emergency (“fight or flight”)	Promotes relaxation, nutrient uptake, energy storage (“rest and digest”)

Summary of the Sympathetic Division

16 To summarize:

- The sympathetic division of the ANS includes two sets of sympathetic chain ganglia, one on each side of the vertebral column; three collateral ganglia anterior to the vertebral column; and two adrenal medullae.
- The preganglionic fibers are short because the ganglia are close to the spinal cord. The postganglionic fibers are longer and extend a considerable distance to their target organs. (In the case of the adrenal medullae, very short axons end at capillaries that carry their secretions to the bloodstream.)
- The sympathetic division shows extensive divergence. That is, a single preganglionic fiber may innervate (form synapses with) two dozen or more ganglionic neurons in different ganglia. As a result, a single sympathetic motor neuron in the CNS can control a variety of visceral effectors and can produce a complex and coordinated response.
- All preganglionic neurons release ACh at their synapses with ganglionic neurons. Most postganglionic fibers release NE, but some release ACh or NO.
- The effector response depends on the second messengers triggered by G protein activation when NE or E binds to alpha receptors or beta receptors.

Summary of the Parasympathetic Division

To summarize:

- The parasympathetic division includes visceral motor nuclei associated with cranial nerves III, VII, IX, and X, and with sacral segments S₂–S₄.
- Ganglionic neurons are found in ganglia within or next to their target organs.

- The parasympathetic division innervates regions serviced by the cranial nerves and organs enclosed by the thoracic and abdominopelvic cavities.
- The parasympathetic division has approximately one-fifth as much divergence as the sympathetic division.
- All parasympathetic neurons are cholinergic. Ganglionic neurons have nicotinic receptors, which are excited by ACh. Muscarinic receptors at neuromuscular or neuroglandular junctions produce either excitation or inhibition, depending on the action of enzymes triggered by G protein activation when ACh binds to the receptor.
- The effects of parasympathetic stimulation are generally brief and restricted to specific organs and sites.

Let's explore next how these different functions provide coordinated responses to changing bodily environments.

Checkpoint

13. Compare the anatomy of the sympathetic division with that of the parasympathetic division.
14. Compare the amount of divergence of the sympathetic division with the parasympathetic division and explain the significance of divergence.

See the blue Answers tab at the back of the book.

16-7 Dual innervation of organs allows the sympathetic and parasympathetic divisions to coordinate vital functions

Learning Outcome Discuss the functional significance of dual innervation and autonomic tone.

Some organs are innervated by either the sympathetic or parasympathetic division, but most vital organs receive **dual innervation**,

so they receive instructions from both divisions. Where dual innervation exists, the two divisions commonly have opposing effects. Dual innervation with opposing effects is most obvious in the digestive tract, heart, and lungs. At other sites, the responses may be separate or complementary. **Table 16-3** provides a functional comparison of the two divisions, noting the effects of sympathetic or parasympathetic activity on specific organs and systems. We also discuss *autonomic tone*, the background level of ANS activation, both with and without dual innervation.

Anatomy of Dual Innervation

Parasympathetic preganglionic fibers travel by cranial nerves to the ciliary, pterygopalatine, submandibular, and otic ganglia, and from there postganglionic fibers travel to their peripheral destinations. Sympathetic postganglionic fibers

reach the same destinations by traveling directly from the superior cervical ganglia of the sympathetic chain.

In the thoracic and abdominopelvic cavities, the sympathetic postganglionic fibers mingle with parasympathetic preganglionic fibers, forming a series of nerve networks collectively called *autonomic plexuses*. Nerves leaving these networks travel with the blood vessels and lymphatic vessels that supply visceral organs.

Autonomic fibers entering the thoracic cavity intersect at the **cardiac plexus** and the **pulmonary plexus** (**Figure 16-6**). These plexuses contain sympathetic and parasympathetic fibers to the heart and lungs, respectively, as well as the parasympathetic ganglia whose output affects those organs. The **esophageal plexus** contains descending branches of the vagus nerves and splanchnic nerves leaving the sympathetic chain on either side.

Figure 16-6 The Autonomic Plexuses and Ganglia.

Table 16–3 A Functional Comparison of the Sympathetic and Parasympathetic Divisions of the ANS

Structure	Sympathetic Effects (receptor or synapse type)	Parasympathetic Effects (all muscarinic receptors)
EYE	Dilation of pupil (α_1); accommodation for distance vision (β_2)	Constriction of pupil; accommodation for close vision
Lacrimal glands	None (not innervated)	Secretion
SKIN		
Sweat glands	Increased secretion, palms and soles (α_1); generalized increase in secretion (cholinergic)	None (not innervated)
Arrector pili muscles	Contraction; erection of hairs (α_1)	None (not innervated)
CARDIOVASCULAR SYSTEM		
Blood vessels		None (not innervated)
To skin	Dilation (β_2 and cholinergic); constriction (α_1)	None (not innervated)
To skeletal muscles	Dilation (β_2 and cholinergic; nitroxidergic)	None (not innervated)
To heart	Dilation (β_2); constriction (α_1 , α_2)	None (not innervated)
To lungs	Dilation (α_2); constriction (α_1)	None (not innervated)
To digestive viscera	Constriction (β_2); dilation (α_2)	None (not innervated)
To kidneys	Constriction, decreased urine production (α_1 , α_2); dilation, increased urine production (β_1 , β_2)	None (not innervated)
To brain	Dilation (cholinergic and nitroxidergic)	None (not innervated)
Veins	Constriction (α_1 , β_2)	None (not innervated)
Heart	Increased heart rate, force of contraction, and blood pressure (α_1 , β_1)	Decreased heart rate, force of contraction, and blood pressure
ENDOCRINE SYSTEM		
Adrenal gland	Secretion of epinephrine, norepinephrine by adrenal medulla	None (not innervated)
Posterior lobe of pituitary gland	Secretion of ADH (β_1 , β_2)	None (not innervated)
Pancreas	Decreased insulin secretion (α_2)	Increased insulin secretion
Pineal gland	Increased melatonin secretion (β_1 , β_2)	Inhibition of melatonin synthesis
RESPIRATORY SYSTEM		
Airways	Increased airway diameter (β_2)	Decreased airway diameter
Secretory glands	Mucus secretion (α_1)	None (not innervated)
DIGESTIVE SYSTEM		
Salivary glands	Production of viscous secretion (α_1 , β_1) containing mucins and enzymes	Production of copious, watery secretion
Sphincters	Constriction (α_1)	Dilation
General level of activity	Decreased (α_2 , β_2)	Increased
Secretory glands	Inhibition (α_2)	Stimulation
Liver	Glycogen breakdown, glucose synthesis and release (α_1 , β_2)	Glycogen synthesis
Pancreas	Decreased exocrine secretion (α_1)	Increased exocrine secretion
SKELETAL MUSCLES		
	Increased force of contraction, glycogen breakdown (β_2)	None (not innervated)
	Facilitation of ACh release at neuromuscular junction (α_2)	None (not innervated)
ADIPOSE TISSUE	Lipolysis, fatty acid release (α_1 , β_1 , β_3)	None (not innervated)
URINARY SYSTEM		
Kidneys	Secretion of renin (β_1)	Uncertain effects on urine production
Urinary bladder	Constriction of internal sphincter; relaxation of urinary bladder (α_1 , β_2)	Tensing of urinary bladder, relaxation of internal sphincter to eliminate urine
MALE REPRODUCTIVE SYSTEM		
	Increased glandular secretion and ejaculation (α_1)	Erection
FEMALE REPRODUCTIVE SYSTEM		
	Increased glandular secretion; contraction of pregnant uterus (α_1)	Variable (depending on hormones present)
	Relaxation of nonpregnant uterus (β_2)	Variable (depending on hormones present)

Parasympathetic preganglionic fibers of the vagus nerves enter the abdominopelvic cavity with the esophagus. There the fibers enter the **celiac plexus**, also known as the *solar plexus*. The celiac plexus and associated smaller plexuses, such as the **inferior mesenteric plexus**, innervate viscera within the abdominal cavity (**Figure 16–6**). The **hypogastric plexus** innervates the digestive, urinary, and reproductive organs of the pelvic cavity. This plexus contains the parasympathetic outflow of the pelvic nerves, sympathetic postganglionic fibers from the inferior mesenteric ganglion, and splanchnic nerves from the sacral sympathetic chain.

Autonomic Tone

Even without stimuli, autonomic motor neurons show a resting level of spontaneous activity. This background level of activity determines an individual's **autonomic tone**. Autonomic tone is an important aspect of ANS function, just as muscle tone is a key aspect of SNS function. If a nerve is inactive under normal conditions, then all it can do is increase its activity on demand. But if the nerve maintains a continual background level of activity, then it can increase or decrease its activity, providing a greater range of control options.

Autonomic tone is significant where dual innervation occurs and the two ANS divisions have opposing effects. It is even more important where dual innervation does not occur. To demonstrate how autonomic tone affects ANS function, let's consider one example of each situation.

The heart receives dual innervation. Recall that the heart consists of cardiac muscle tissue, and that specialized pacemaker cells trigger its contractions. The two autonomic divisions have opposing effects on heart function. Acetylcholine (ACh), released by postganglionic fibers of the parasympathetic division, causes a reduction in heart rate. Norepinephrine (NE), released by varicosities of the sympathetic division, accelerates heart rate. Small amounts of both neurotransmitters are released continuously, creating autonomic tone. However, the parasympathetic division dominates under resting conditions. Heart rate can be controlled very precisely to meet the demands of active tissues through small adjustments in the balance between parasympathetic and sympathetic stimulation. In a crisis, stimulation of the sympathetic innervation and inhibition of the parasympathetic innervation accelerate the heart rate to the maximum extent possible.

The sympathetic control of blood vessel diameter demonstrates how autonomic tone allows fine adjustment of peripheral activities in target organs that are innervated by only one ANS division. Blood flow to specific organs must be controlled to meet the tissue demands for oxygen and nutrients. When a blood vessel dilates, blood flow through it increases; when it constricts, blood flow is reduced. Sympathetic postganglionic fibers release NE at the smooth muscle cells in the walls of peripheral vessels. This background sympathetic tone keeps these muscles partially contracted, so the blood vessels are ordinarily at about half their

maximum diameter. When increased blood flow is needed, the rate of NE release decreases and sympathetic cholinergic fibers are stimulated. As a result, the smooth muscle cells relax, the vessels dilate, and blood flow increases. By adjusting sympathetic tone and the activity of cholinergic fibers, the sympathetic division can exert precise control of vessel diameter over its entire range.

✓ Checkpoint

15. List general responses to increased sympathetic activity and to parasympathetic activity.
16. What effect would the loss of sympathetic tone have on blood flow to a tissue?
17. What physiological changes are expected in a patient who is about to undergo a dental root canal and is quite anxious about the procedure?

See the blue Answers tab at the back of the book.

16-8 Various levels of autonomic regulation allow for the integration and control of autonomic functions

Learning Outcome Describe the hierarchy of interacting levels of control in the autonomic nervous system, including the significance of visceral reflexes.

Recall that centers involved in somatic motor control are found in all portions of the central nervous system, from lower motor neurons involved in cranial and spinal reflex arcs to the pyramidal motor neurons of the primary motor cortex. Similarly, the autonomic nervous system is also organized into a series of interacting levels. At the lowest level are visceral motor neurons in the lower brainstem and spinal cord that are involved in cranial and spinal visceral reflexes. A **visceral reflex** is an autonomic pathway that produces a response in glands or nonskeletal muscle organs, such as blood vessels, the heart, and digestive tract structures. As in the sympathetic nervous system, autonomic nervous system simple reflexes based in the spinal cord respond rapidly and automatically to stimuli. At the highest level, centers in the brainstem that regulate specific visceral functions control the levels of activity of the sympathetic and parasympathetic divisions.

Visceral Reflexes

Visceral reflexes provide automatic motor responses that can be modified, facilitated, or inhibited by higher centers, especially those of the hypothalamus. For example, when a light is shone in one eye, a visceral reflex constricts the pupils of *both* eyes (the *consensual light reflex*). The visceral motor commands are distributed by parasympathetic fibers. In darkness, pupils dilate, but this *pupillary reflex* is directed by sympathetic fibers. However, the motor nuclei directing pupillary constriction or dilation are also controlled by hypothalamic centers concerned with emotional states. For example, being queasy or nauseated, causes the pupils to constrict. During sexual arousal, the pupils dilate.

Figure 16–7 Visceral Reflexes. Visceral reflexes have the same basic components as somatic reflexes, but all visceral reflexes are polysynaptic. Note that short visceral reflexes bypass the CNS altogether.

? The short reflex bypasses what part of the nervous system?

The ganglia in the walls of the digestive tract contain the cell bodies of visceral sensory neurons, interneurons, and visceral motor neurons, and all their axons form extensive nerve nets. Parasympathetic innervation by visceral motor neurons can stimulate and coordinate various digestive activities, but the enteric nervous system can control digestive functions independent of the CNS. We consider the functions of the enteric nervous system further in Chapter 24.

As we examine other body systems in later chapters, you will come across many examples of autonomic reflexes involved in respiration, cardiovascular function, and other visceral activities. **Table 16–4** previews some of the most important ones. Notice that the parasympathetic division participates in a variety of reflexes that affect individual organs and systems. This specialization reflects its relatively restricted pattern of innervation. In contrast, fewer sympathetic reflexes exist. The whole sympathetic division is typically activated. One reason is that it has such a high degree of divergence. Another reason is that the release of hormones by the adrenal medullae produces widespread peripheral effects.

Each **visceral reflex arc** consists of a receptor, a sensory neuron, a processing center (one or more interneurons), and two visceral motor neurons (**Figure 16–7**). All visceral reflexes are polysynaptic. They can be *long reflexes* or *short reflexes*.

Long reflexes are the autonomic equivalents of the polysynaptic reflexes introduced in Chapter 13. Visceral sensory neurons deliver information to the CNS. It travels along the posterior roots of spinal nerves, within the sensory branches of cranial nerves, and within the autonomic nerves that innervate visceral effectors. The processing steps involve interneurons within the CNS. The ANS then carries the motor commands to the appropriate visceral effectors. Long reflexes typically coordinate the activities of an entire organ.

Short reflexes bypass the CNS entirely. They involve sensory neurons and interneurons whose cell bodies lie in autonomic ganglia. These interneurons synapse on postganglionic neurons, and their postganglionic fibers distribute the motor commands. Short reflexes control very simple motor responses with localized effects. In general, short reflexes may control patterns of activity in one small part of a target organ.

In most organs, long reflexes are most important in regulating visceral activities, but this is not the case with the digestive tract and its associated glands. In these areas, short reflexes provide most of the control and coordination for normal functioning. The neurons involved form the enteric nervous system.

Higher Levels of Autonomic Control

Processing centers in the medulla oblongata of the brainstem coordinate more complex sympathetic and parasympathetic reflexes. In addition to the cardiovascular and respiratory centers, the medulla oblongata contains centers and nuclei involved with salivation, swallowing, digestive secretions, peristalsis, and urinary function. These centers are in turn subject to regulation by the hypothalamus.

The term *autonomic* was originally applied because the regulatory centers involved with the control of visceral function were thought to operate autonomously—that is, independent of other central nervous system activities. We now know that because the hypothalamus interacts with all other areas of the brain, activity in the limbic system, thalamus, or cerebral cortex can have effects on autonomic function. For example, what happens when someone becomes angry? Their heart rate accelerates, blood pressure rises, and respiratory rate increases. What happens when a person thinks about their next meal? Their stomach “growls” and mouth waters.

The Integration of ANS and SNS Activities

Figure 16–8 and **Table 16–5** show how the activities of the autonomic nervous system and the somatic nervous system are integrated. We have considered visceral and somatic motor

Table 16–4 Representative Visceral Reflexes

Reflex	Stimulus	Response	Comments
PARASYMPATHETIC REFLEXES			
Gastric and intestinal reflexes (Chapter 24)	Pressure and physical contact	Smooth muscle contractions that propel food materials and mix with secretions	Initiated by vagus nerves and controlled locally by ENS
Defecation (Chapter 24)	Distention of rectum	Relaxation of internal anal sphincter	Requires voluntary relaxation of external anal sphincter
Urination (Chapter 26)	Distention of urinary bladder	Contraction of walls of urinary bladder; relaxation of internal urethral sphincter	Requires voluntary relaxation of external urethral sphincter
Consensual light response (Chapter 14)	Bright light shining in eye(s)	Constriction of pupils of both eyes	
Swallowing reflex (Chapter 24)	Movement of food and liquids into pharynx	Smooth muscle and skeletal muscle contractions	Coordinated by medullary swallowing center
Coughing reflex (Chapter 23)	Irritation of respiratory tract	Sudden explosive ejection of air	Coordinated by medullary coughing center
Baroreceptor reflex (Chapters 17, 20, 21)	Sudden rise in carotid blood pressure	Reduction in heart rate and force of contraction	Coordinated in cardiac centers of medulla oblongata
Sexual arousal (Chapter 28)	Erotic stimuli (visual or tactile)	Increased glandular secretions, sensitivity, erection	
SYMPATHETIC REFLEXES			
Cardioacceleratory reflex (Chapter 21)	Sudden decrease in blood pressure in carotid artery	Increase in heart rate and force of contraction	Coordinated in cardiac centers of medulla oblongata
Vasomotor reflexes (Chapter 21)	Changes in blood pressure in major arteries	Changes in diameter of peripheral vessels	Coordinated in vasomotor center in medulla oblongata
Pupillary light reflex (Chapter 17)	Light striking photoreceptors in one eye	Dilation of pupil	
Ejaculation (in males) (Chapter 28)	Erotic stimuli (tactile)	Skeletal muscle contractions ejecting semen	

Table 16–5 A Comparison of the ANS and SNS

Characteristic	ANS	SNS
Innervation	Visceral effectors, including cardiac muscle, smooth muscle, glands, adipocytes	Skeletal muscles
Activation	In response to sensory stimuli or from commands of higher centers	In response to sensory stimuli or from commands of higher centers
Relay and processing centers	Brainstem	Brainstem and thalamus
Headquarters	Hypothalamus	Cerebral cortex
Feedback received from	Limbic system and thalamus	Cerebellum and basal nuclei
Control method	Adjustment of activity in brainstem processing centers that innervate preganglionic neurons	Direct (corticospinal) and indirect (medial and lateral) pathways that innervate lower motor neurons
Reflexes	Polysynaptic (short and long)	Monosynaptic and polysynaptic (always long)

pathways separately, but the two have many parallels, in terms of both organization and function. Integration takes place at the level of the brainstem, and both systems are under the influence of higher centers.

✓ Checkpoint

18. Define visceral reflex.
19. Luke has a brain tumor that is interfering with the function of his hypothalamus. Explain why this tumor would interfere with autonomic function.

See the blue Answers tab at the back of the book.

16-9 Higher-order functions include memory and states of consciousness, and neurotransmitters influence behavior

Learning Outcome Explain how memories are created, stored, and recalled; distinguish among the levels of consciousness and unconsciousness; and describe how neurotransmitters influence brain function.

Higher-order functions share three characteristics:

- The cerebral cortex is required for their performance. They involve complex interactions among areas of the cortex and between the cortex and other areas of the brain.

Figure 16-8 A Comparison of Somatic and Autonomic Function. The SNS and ANS have parallel organization and are integrated at the level of the brainstem. Blue arrows indicate ascending sensory information; red arrows indicate descending motor commands; dashed lines indicate pathways of communication and feedback among higher centers.

- They involve both conscious and unconscious information processing.
- Higher-order functions are subject to adjustment over time. They are not innate (inborn), fixed reflexive behaviors.

In Chapter 14, we considered functional areas of the cerebral cortex and discussed hemispheric lateralization. In this section, we consider the mechanisms of memory and learning. We also describe the neural interactions responsible for consciousness, sleep, and arousal.

Memory

What was the topic of the last sentence? What is the name of a good friend? To answer these questions, memory is accessed. **Memories** are stored bits of information gathered through experience. **Fact memories** are specific bits of information,

such as the color of a stop sign or the smell of a perfume. **Skill memories** are learned motor behaviors, such as riding a bike. With repetition, skill memories become incorporated at the unconscious level. Skill memories related to innate behaviors, such as eating, are stored in appropriate portions of the brainstem. Complex skill memories, such as how to ski or play the violin, involve the integration of motor patterns in the basal nuclei, cerebral cortex, and cerebellum.

Two classes of memories are recognized, short term and long term (Figure 16-9). **Short-term memories** do not last long, but while they persist the information can be recalled immediately. Short-term memories contain small bits of information, such as a person's name or a telephone number. Repeating a phone number or other bit of information reinforces the original short-term memory and allows it to be converted to a long-term memory.

Long-term memories last much longer, in some cases for an entire lifetime. The conversion from short-term to long-term memory is called **memory consolidation**. There are two types of long-term memory: (1) *Secondary memories* are long-term memories that fade with time and may require considerable effort to recall. (2) *Tertiary memories* are

long-term memories that remain for a lifetime, such as your name or the contours of your own body.

Brain Regions Involved in Memory Consolidation and Access

The amygdaloid body (amygdala) and the hippocampus, two components of the limbic system (Figure 14-12), are essential to memory consolidation. Damage to the hippocampus leads to an inability to convert short-term memories to new long-term memories, although existing long-term memories remain intact and accessible. Tracts leading from the amygdaloid body to the hypothalamus may link memories to specific emotions.

The **nucleus basalis**, a cerebral nucleus near the diencephalon, plays an uncertain role in memory storage and retrieval. Tracts connect this nucleus with the hippocampus,

Figure 16–9 Memory Storage. Steps in the storage of memories and the conversion from short-term memory to long-term memory.

amygdaloid body, and all areas of the cerebral cortex. Damage to this nucleus is associated with changes in emotional states, memory, and intellectual function (as described in the discussion of Alzheimer's disease later in this chapter).

Most long-term memories are stored in the cerebral cortex. Conscious motor and sensory memories are referred to the appropriate association areas. For example, visual memories are stored in the visual association area, and memories of voluntary motor activity are stored in the premotor cortex. Special portions of the occipital and temporal lobes are crucial to the memories of faces, voices, and words.

In at least some cases, a specific memory probably depends on the activity of a single neuron. For example, in one portion of the temporal lobe an individual neuron responds to the sound of one word and ignores others. A specific neuron may also be activated by the proper combination of sensory stimuli associated with a particular individual, such as kind grandmothers. As a result, these neurons are called "grandmother cells."

Information on one subject is parceled out to many different regions of the brain. For example, memories of dogs are stored in the visual association area (what a dog looks like, that the letters *d-o-g* mean "dog"), the auditory association area (the "woof" sound that a dog makes), the speech center (how the word *dog* is said), and the frontal lobes (how big dogs are and what they eat). Related information, such as emotions about dogs and what dogs feel like, is stored in other locations. If one of those storage areas is damaged, memory will be incomplete in some way. How these memories are accessed and assembled on demand remains an area of active research.

Cellular Mechanisms of Memory Formation and Storage

Memory consolidation at the cellular level involves anatomical and physiological changes in neurons and synapses. For legal, ethical, and practical reasons, scientists do not conduct much research on these mechanisms with human subjects. Research on other animals, commonly those with relatively simple nervous systems, has indicated that the following mechanisms may be involved:

- **Increased Neurotransmitter Release.** A synapse that is frequently active increases the amount of neurotransmitter it stores, and it releases more with each stimulation. The more neurotransmitter released, the greater the effect on the postsynaptic neuron.

- **Facilitation at Synapses.** When a neural circuit is repeatedly

activated, the axon terminals begin continuously releasing neurotransmitter in small quantities. The neurotransmitter binds to receptors on the postsynaptic membrane, producing a graded depolarization that brings the membrane closer to threshold. The facilitation that results affects all neurons in the circuit.

- **The Formation of Additional Synaptic Connections.** When one neuron repeatedly communicates with another, the axon tip branches and forms additional synapses on the postsynaptic neuron. As a result, stimulation of the presynaptic neuron has a greater effect on the membrane potential of the postsynaptic neuron.

Such processes create anatomical changes that facilitate communication along a specific neural circuit. This facilitated communication is thought to be the basis of memory storage. A single circuit that corresponds to a single memory has been called a **memory engram**. This definition is based on function rather than structure. We know too little about the organization and storage of memories to be able to describe the neural circuits involved. Memory engrams form as the result of experience and repetition. Repetition is crucial—that's why you probably need to read these chapters more than once before an exam!

Efficient conversion of a short-term memory into a memory engram takes time, usually at least an hour. Whether that conversion will occur depends on several factors. They include the nature, intensity, and frequency of the original stimulus. Very strong, repeated, or exceedingly pleasant or unpleasant events are most likely to be converted to long-term memories.

+ Clinical Note Insomnia

Insomnia (literally, “no sleep”) includes trouble falling asleep, frequent awakenings with trouble falling back to sleep, and poor sleep quality. One in 10 adults in the United States (more commonly females and older adults) experiences chronic insomnia. This condition is more than a mere nuisance. Insomnia results in physical and mental disorders, job and relationship dysfunction, and diminished quality of life. The person with insomnia also experiences constant hyperarousal, including an increased heart rate, elevated blood pressure, increased muscle tone, and disturbed sleep pattern, due to an overactive sympathetic nervous system.

Insomnia can be treated both medically and psychologically. An overnight sleep study can be used to collect objective data about sleep habits and behaviors. In such a study, sleep technicians record brain activity patterns. Psychologists use the “3P” model to evaluate insomnia: **p**redisposing factors (such as genetics and anxious personality type), **p**recipitating factors (such as a stressful life event), and **p**erpetuating factors (such as substance abuse and poor preparation for sleep). All this information is then used for a treatment plan.

Drugs that stimulate the CNS, such as caffeine and nicotine, may enhance memory consolidation through facilitation. We discussed the membrane effects of those drugs in Chapter 12.

The hippocampus plays a key role in consolidating memories. The mechanism remains unknown, but it is linked to the presence of *NMDA* (*N*-methyl-D-aspartate) *receptors*, which are chemically gated calcium ion channels. When activated by the neurotransmitter *glutamate*, the gates open and calcium ions enter the cell. Blocking NMDA receptors in the hippocampus prevents long-term memory formation.

States of Consciousness

The difference between a conscious individual and an unconscious one might seem obvious. A conscious individual is alert and attentive, and an unconscious individual is not. Yet there are many degrees of both states. *Conscious* implies an awareness of and attention to external events and stimuli, but a healthy conscious person can be nearly asleep, wide awake, or high-strung and jumpy. *Unconscious* can refer to conditions ranging from the deep, unresponsive state induced by anesthesia before major surgery, to deep sleep, to the light, drifting “nod” that occasionally plagues students who are reading anatomy and physiology textbooks or listening to audiobooks.

A person’s degree of wakefulness at any moment indicates the level of ongoing CNS activity. When a person is asleep, they are unconscious but can still be awakened by normal sensory stimuli. Healthy individuals cycle between the alert, conscious state and sleep each day. When central nervous system function

becomes abnormal or depressed, the state of wakefulness can be affected. An individual in a *coma*, for example, is unconscious and cannot be awakened, even by strong stimuli.

Sleep

We recognize two general levels of sleep, *deep* and *REM sleep*, each with characteristic patterns of brain wave activity (**Figure 16–10a**):

- In **deep sleep**, also called *slow wave* or *non-REM (NREM) sleep*, the entire body relaxes, and activity at the cerebral cortex is at a minimum. Heart rate, blood pressure, respiratory rate, and energy use decrease by up to 30%.

Figure 16–10 States of Sleep.

- a** An EEG of the various sleep states. The EEG pattern during REM sleep resembles the alpha waves typical of awake adults.

- b** Typical pattern of sleep stages in a healthy young adult during a single night's sleep.

- During **rapid eye movement (REM) sleep**, a person dreams actively, and blood pressure and respiratory rate change. Although an EEG taken during REM sleep resembles that of the awake state, they become even less receptive to outside stimuli than in deep sleep, and muscle tone decreases markedly. Intense inhibition of somatic motor neurons probably prevents a person from acting out the responses they envision while dreaming. The neurons controlling eye muscles escape this inhibitory influence, and their eyes move rapidly as dream events unfold.

Periods of REM and deep sleep alternate throughout the night, beginning with deep sleep for about an hour and a half (**Figure 16-10b**). REM periods initially average about 5 minutes, but over an 8-hour night they gradually increase to about 20 minutes. Each night people probably spend less than 2 hours dreaming, but variation among individuals is significant. For example, children spend more time in REM sleep than do adults, and extremely tired individuals have very short and infrequent REM periods.

Sleep produces only minor changes in the physiological activities of other organs and systems, and none of these changes appear to be essential to normal function. The significance of sleep must lie in its impact on the CNS, but the physiological or biochemical basis remains to be determined. We do know that protein synthesis in neurons increases during sleep.

Extended periods without sleep lead to a variety of disturbances in mental function. Approximately 25% of the U.S. population experiences some form of *sleep disorder*. Examples include abnormal patterns or duration of REM sleep or unusual behaviors during sleep, such as sleepwalking. In some cases, these problems affect the individual's conscious activities. Slowed reaction times, irritability, and behavioral changes may result. Memory loss has also been linked to sleep disorders.

Arousal and the Reticular Activating System

Arousal, or awakening from sleep, appears to be one of the functions of the reticular formation. The reticular formation is especially well suited for providing “watchdog” services because it has extensive interconnections with the sensory, motor, and integrative nuclei and pathways all along the brainstem.

The state of consciousness results from complex interactions between the reticular formation and the cerebral cortex. One of the most important brainstem components is the **reticular activating system (RAS)**. This diffuse network in the reticular formation extends from the medulla oblongata to the midbrain (**Figure 16-11**). The output of the RAS projects to thalamic nuclei that influence large areas of the cerebral cortex. When the RAS is inactive, so is the cerebral cortex, and stimulation of the RAS produces a widespread activation of the cerebral cortex.

The midbrain portion of the RAS appears to be the “headquarters” of the system. Stimulating this area produces the most

pronounced and long-lasting effects on the cerebral cortex. Stimulating other portions of the RAS seems to have an effect only to the degree that it changes the activity of the midbrain region. The greater the stimulation to the midbrain region of the RAS, the more alert and attentive the individual will be to incoming sensory information. The thalamic nuclei associated with the RAS may also play an important role in focusing attention on specific mental processes.

Sleep may be ended by any stimulus sufficient to activate the reticular formation and RAS. Arousal occurs rapidly, but the effects of a single stimulation of the RAS last less than a minute. After that, consciousness can be maintained by positive feedback, because activity in the cerebral cortex, basal nuclei, and sensory and motor pathways will continue to stimulate the RAS.

After many hours of activity, the reticular formation becomes less responsive to stimulation. The body becomes less alert and more lethargic. The precise mechanism remains unknown, but neural fatigue probably plays a relatively minor role in the decreasing RAS activity. Evidence suggests that the regulation of sleep-wake cycles involves an interplay between brainstem nuclei that use different neurotransmitters. One group of nuclei stimulates the RAS with norepinephrine and maintains the awake, alert state. Another group depresses RAS activity with serotonin, promoting deep sleep. These “dueling” nuclei are in the brainstem.

Figure 16-11 The Reticular Activating System (RAS). The midbrain “headquarters” of the reticular formation receives collateral inputs from a variety of sensory pathways. Stimulation of this region produces arousal and heightened states of attentiveness.

Special sensory inputs arrive by which cranial nerves?

Clinical Note Summary of Nervous System Disorders

Nervous tissue is extremely delicate. The characteristics of its extracellular environment must be kept within narrow homeostatic limits. Signs and symptoms of neurological disorders appear when homeostatic regulatory mechanisms break down. This may happen under the stress of genetic or environmental factors, infection, or trauma.

Literally hundreds of disorders affect the nervous system. They can be categorized as the following:

- *Infections*, which include diseases such as rabies, meningitis, and polio
- *Congenital disorders*, such as spina bifida and hydrocephalus
- *Degenerative disorders*, such as Parkinson's disease and Alzheimer's disease
- *Tumors* of neural origin
- *Trauma*, such as spinal cord injuries and concussions
- *Toxins*, such as heavy metals and the neurotoxins found in certain seafoods
- *Secondary disorders*, which are problems resulting from dysfunction in other systems, for example, strokes and several demyelination disorders.

A standard physical examination includes a neurological component. The physician checks the general status of the central nervous system and the peripheral nervous system. In a *neurological examination*, a physician attempts to trace the location of a specific problem by evaluating the sensory, motor, behavioral, and cognitive functions of the nervous system.

Influence of Neurotransmitters on Brain Chemistry and Behavior

Changes in the normal balance between two or more neurotransmitters can profoundly affect brain function and so behavior. For example, the interplay between populations of neurons releasing norepinephrine and serotonin appears to be involved in regulating sleep-wake cycles. Another example is provided by the inherited disease called *Huntington's disease*, which involves the unexplained destruction of ACh-secreting and gamma aminobutyric acid (GABA)-secreting neurons in the basal nuclei. Symptoms appear as the basal nuclei and frontal lobes slowly degenerate. A person with Huntington's disease has difficulty controlling movements, and intellectual abilities gradually decrease. In many cases, the importance of a specific neurotransmitter was revealed while searching for the mechanism of action of other drugs. Three examples follow.

- *Serotonin*. An extensive network of tracts delivers serotonin to nuclei and higher centers throughout the brain, and variations in the serotonin level affect sensory interpretation

and emotional states. Compounds that enhance the effects of serotonin produce hallucinations. For instance, *lysergic acid diethylamide* (LSD) is a powerful hallucinogenic drug that activates serotonin receptors in the brainstem, hypothalamus, and limbic system. Compounds that merely enhance the effects of serotonin also produce hallucinations, whereas compounds that inhibit serotonin production or block its action cause severe depression and anxiety. An effective antidepressant now in widespread use, *fluoxetine* (Prozac), slows the removal of serotonin at synapses, causing an increase in the serotonin concentration at the postsynaptic membrane. Such drugs are classified as selective serotonin reuptake inhibitors (SSRIs). Other important SSRIs include *Celexa*, *Luvox*, *Paxil*, and *Zoloft*.

- *Norepinephrine*. Norepinephrine (NE) has pathways throughout the brain. Drugs that stimulate norepinephrine release cause exhilaration, while those that depress its release cause depression. One inherited form of depression has been linked to a defective enzyme involved in norepinephrine synthesis.
- *Dopamine*. Disturbances in dopamine transmission have been linked to several neurological disorders. We have already seen that inadequate dopamine causes the motor problems of Parkinson's disease. Excessive production of dopamine may be associated with *schizophrenia*, a psychological disorder marked by pronounced disturbances of mood, thought patterns, and behavior. Amphetamines, or "speed," stimulate dopamine secretion and, in large doses, can produce symptoms resembling those of schizophrenia. Dopamine is thus important not only in the nuclei involved in the control of intentional movements, but also in many other centers of the diencephalon and cerebrum.

Checkpoint

20. List three characteristics of higher-order functions.
21. Recalling facts while taking an A&P test uses which type of memory?
22. What would happen if a person's reticular activating system were suddenly stimulated while they were sleeping?
23. What would be an effect of a drug that substantially increases the amount of serotonin released in the brain?
24. Amphetamines stimulate the secretion of which neurotransmitter?

See the blue Answers tab at the back of the book.

16-10 Aging produces various structural and functional changes in the nervous system

Learning Outcome Summarize the effects of aging on the nervous system and give examples of interactions between the nervous system and other organ systems.

The aging process affects all body systems, and the nervous system is no exception. Anatomical and physiological changes probably begin by age 30 and accumulate over time. An estimated 85% of people above age 65 lead relatively normal lives, but they exhibit noticeable changes in mental performance and in central nervous system function. Common age-related anatomical changes in the nervous system include the following:

- **Reduction in Brain Size and Weight.** This reduction results primarily from a decrease in the volume of the cerebral cortex. The brains of older individuals have narrower gyri and wider sulci than do those of young people, and the subarachnoid space is larger.
- **Reduction in the Number of Neurons.** Brain shrinkage has been linked to a loss of cortical neurons, although evidence indicates that neurons are not lost (at least to the same degree) in brainstem nuclei.
- **Decrease in Blood Flow to the Brain.** With age, fatty deposits gradually build up in the walls of blood vessels. Just as a clog in a drain reduces water flow, these deposits reduce the rate of blood flow through arteries. (This process, called *arteriosclerosis*, affects arteries throughout the body. Even if the reduction in blood flow is not large enough to damage neurons, arteriosclerosis increases the chances that the affected vessel wall will rupture, damaging the surrounding nervous tissue and producing signs and symptoms of a *cerebrovascular accident (CVA)*, also called a *stroke*.)
- **Changes in the Synaptic Organization of the Brain.** In many areas, the number of dendritic branches, spines, and interconnections appears to decrease. Synaptic connections are lost, and the rate of neurotransmitter production decreases.
- **Intracellular and Extracellular Changes in CNS Neurons.** Many neurons in the brain accumulate abnormal intracellular deposits, including lipofuscin and neurofibrillary tangles. **Lipofuscin** is a granular pigment with no known function. **Neurofibrillary tangles** are masses of neurofibrils that form dense mats inside the cell body and axon. **Plaques** are extracellular accumulations of fibrillar proteins, surrounded by abnormal dendrites and axons. Both plaques and tangles contain deposits of several peptides—primarily two forms of **serum amyloid A protein**, fibrillar and soluble. They appear in brain regions such as the hippocampus, specifically associated with memory processing. Their significance is unknown. Evidence indicates that they appear in all aging brains. In excess, they seem to be associated with clinical abnormalities.

The anatomical changes associated with aging of the nervous system affect all neural functions. For example, memory consolidation typically becomes more difficult, and secondary memories, especially those of the recent past, become harder to access. As aging occurs, sensory systems—notably, hearing, balance, vision, smell, and taste—become less sensitive. Lights

must be brighter, sounds louder, and smells stronger before they are perceived. Reaction rates are slowed, and reflexes—even some withdrawal reflexes—weaken or disappear. Motor control precision decreases, and it takes longer for an older person to perform a given motor pattern than it did 20 years earlier.

For about 85% of aging adults, these changes do not interfere with their abilities to function in society. But for reasons yet unknown, some individuals become incapacitated by progressive CNS changes. These degenerative changes, which can include memory loss, anterograde amnesia (the inability to remember new information), and emotional disturbances, are often lumped together as **senile dementia**, or *senility*. By far the most common and disabling form of senile dementia is **Alzheimer's disease**.

The relationships between the nervous system and the integumentary, skeletal, and muscular systems are shown in Build Your Knowledge **Figure 16-12**.

✓ Checkpoint

25. What are some possible reasons for the slower recall and loss of memory that occur with age?
26. Identify several common age-related anatomical changes in the nervous system.
27. Name the most common form of senile dementia.
28. Identify the relationships between the nervous system and the body systems studied so far.

See the blue Answers tab at the back of the book.

+ Clinical Note Fainting

A stressful or emotional event may trigger a sudden and overwhelming loss of consciousness, commonly known as *fainting*. The technical term for fainting is the *vasovagal response* (*vaso*, vascular; *vagal*, vagus nerve).

This response is the result of a momentary malfunction of the sympathetic division, causing the parasympathetic division (sometimes called the “faint and freeze” division) to go into overdrive. In this process, parasympathetic stimulation of the vagus nerve causes it to release ACh at the cardiac plexus. However, without any counteracting stimulation from the sympathetic nervous system, the heart rate slows, the force of contractions decreases, and blood pressure drops. As a result, blood flow to the brain decreases, causing the fainting episode.

Rapid recovery begins as soon as the sympathetic division takes over, releasing norepinephrine at the cardiac plexus and throughout the body. Heart rate and blood pressure increase, as does level of consciousness.

To prevent a vasovagal response, a person who feels faint should lie down before they fall. This action will deliver more blood flow to the brain and help prevent an injury.

Figure 16–12 Integration of the NERVOUS system with the other body systems presented so far.

16 Chapter Review

Study Outline

An Introduction to the Autonomic Nervous System and Higher-Order Functions

1. The autonomic nervous system adjusts our basic life support systems without conscious control.

16-1 The autonomic nervous system, which has sympathetic and parasympathetic divisions, is involved in the unconscious regulation of visceral functions

2. The **autonomic nervous system (ANS)** coordinates cardiovascular, respiratory, digestive, urinary, and reproductive functions.
3. **Preganglionic neurons** in the CNS send axons to synapse on **ganglionic neurons** in **autonomic ganglia** outside the CNS. (Figure 16-1)
4. Preganglionic fibers (axons) from the thoracic and lumbar segments form the **sympathetic division**, or *thoracolumbar division* ("fight or flight" system), of the ANS. Preganglionic fibers (axons) leaving the brain and sacral segments form the **parasympathetic division**, or *craniosacral division* ("rest and digest" system).

16-2 The sympathetic division has short preganglionic fibers and long postganglionic fibers and is involved in using energy and increasing metabolic rate

5. The sympathetic division consists of preganglionic neurons between segments T_1 and L_2 , ganglionic neurons in ganglia near the vertebral column, and specialized neurons in the adrenal glands. (Spotlight Figure 16-2a)
6. The two types of sympathetic ganglia are **sympathetic chain ganglia** (*paravertebral ganglia*) and **collateral ganglia** (*prevertebral ganglia*). (Figure 16-3)
7. In spinal segments T_1 – L_2 , anterior roots give rise to the myelinated white ramus communicans, which, in turn, leads to the sympathetic chain ganglia. (Spotlight Figure 16-2a, Figure 16-3)
8. **Postganglionic fibers** targeting structures in the body wall and limbs rejoin the spinal nerves and reach their destinations by way of the posterior and anterior rami. (Spotlight Figure 16-2a, Figure 16-3)
9. Postganglionic fibers targeting structures in the thoracic cavity form **sympathetic nerves**, which go directly to their visceral destinations. Preganglionic fibers run between the sympathetic chain ganglia and interconnect them. (Spotlight Figure 16-2a, Figure 16-3)
10. The abdominopelvic viscera receive sympathetic innervation by preganglionic fibers that synapse within collateral ganglia. The preganglionic fibers that innervate the collateral ganglia form the **splanchnic nerves**. (Spotlight Figure 16-2a, Figure 16-3)

11. The **celiac ganglion** innervates the stomach, liver, gallbladder, pancreas, and spleen; the **superior mesenteric ganglion** innervates the small intestine and initial segments of the large intestine; and the **inferior mesenteric ganglion** innervates the kidneys, urinary bladder, the terminal portions of the large intestine, and the sex organs. (Spotlight Figure 16-2a)
12. Preganglionic fibers entering an adrenal gland synapse within the **adrenal medulla**. (Spotlight Figure 16-2a, Figure 16-3)
13. In a crisis, the entire sympathetic division responds—an event called **sympathetic activation**. Its effects include increased alertness, a feeling of energy and euphoria, increased cardiovascular and respiratory activities, a general elevation in muscle tone, and a mobilization of energy reserves.

16-3 Different types of neurotransmitters and receptors lead to different sympathetic effects

14. The stimulation of the sympathetic division has two distinctive results: the release of either acetylcholine (ACh) or *norepinephrine* (NE) at specific locations, and the secretion of *epinephrine* (E) and NE into the general circulation.
15. Sympathetic ganglionic neurons end in axonal telodendria studded with **varicosities** containing neurotransmitters. (Figure 16-4)
16. The two types of sympathetic receptors are **alpha receptors** and **beta receptors**.
17. Most postganglionic fibers are *adrenergic*; a few are *cholinergic* or *nitroxidergic*. (Table 16-1)
18. The sympathetic division includes two sympathetic chain ganglia, three collateral ganglia, and two adrenal medullae. (Figure 16-5; Tables 16-2, 16-3)

16-4 The parasympathetic division has long preganglionic fibers and short postganglionic fibers and is involved in conserving energy and lowering metabolic rate

19. The parasympathetic division includes preganglionic neurons in the brainstem and sacral segments of the spinal cord, and ganglionic neurons in peripheral ganglia located within (**intramural**) or next to (**terminal**) target organs.
20. Preganglionic fibers leave the brain as components of cranial nerves III, VII, IX, and X. Those leaving the sacral segments form **pelvic nerves**. (Spotlight Figure 16-2b)
21. The effects produced by the parasympathetic division focus on relaxation, food processing, and energy absorption.

16-5 Different types of receptors lead to different parasympathetic effects

22. All parasympathetic preganglionic and postganglionic fibers release ACh. The effects are short lived because ACh is inactivated by *acetylcholinesterase* (AChE) and by *tissue cholinesterase*. (Figure 16-5)
23. Postsynaptic membranes have two types of ACh receptors. The stimulation of **muscarinic receptors** produces a longer-lasting effect than does the stimulation of **nicotinic receptors**. (Table 16-1)

16-6 The differences in the organization of sympathetic and parasympathetic structures lead to widespread sympathetic effects and specific parasympathetic effects

24. The sympathetic division has widespread influence on visceral and somatic structures. (Figure 16-5; Table 16-2)
25. The parasympathetic division innervates areas serviced by cranial nerves and organs in the thoracic and abdominopelvic cavities. (Figure 16-5; Table 16-2)

16-7 Dual innervation of organs allows the sympathetic and parasympathetic divisions to coordinate vital functions

26. The parasympathetic division innervates only visceral structures that are serviced by cranial nerves or enclosed by the thoracic and abdominopelvic cavities. Organs with **dual innervation** receive input from both divisions. (Tables 16-2, 16-3)
27. The parasympathetic and sympathetic nerves intermingle in the thoracic and abdominopelvic cavities to form a series of characteristic *autonomic plexuses* (nerve networks): the **cardiac, pulmonary, esophageal, celiac, inferior mesenteric, and hypogastric plexuses**. (Figure 16-6)
28. Important physiological and functional differences exist between the sympathetic and parasympathetic divisions. (Figure 16-5; Tables 16-2, 16-3)
29. Even when stimuli are absent, autonomic motor neurons show a resting level of activation, the **autonomic tone**.

16-8 Various levels of autonomic regulation allow for the integration and control of autonomic functions

30. **Visceral reflex arcs** perform the simplest function of the ANS and can be either **long reflexes** (with interneurons) or **short reflexes** (bypassing the CNS). (Figure 16-7)

31. Parasympathetic reflexes govern respiration, cardiovascular functions, and other visceral activities. (Table 16-4)
32. Levels of activity in the sympathetic and parasympathetic divisions of the ANS are controlled by centers in the brainstem that regulate specific visceral functions.
33. The SNS and ANS are organized in parallel. Integration occurs at the level of the brainstem and higher centers. (Figure 16-8; Table 16-5)

16-9 Higher-order functions include memory and states of consciousness, and neurotransmitters influence behavior

34. Higher-order functions (1) are performed by the cerebral cortex and involve complex interactions among areas of the cerebral cortex and between the cortex and other areas of the brain, (2) involve conscious and unconscious information processing, and (3) are subject to modification and adjustment over time.
35. Memories can be classified as **short term** or **long term**.
36. The conversion from short-term to long-term memory is **memory consolidation**. (Figure 16-9)
37. **Amnesia** is memory loss resulting from disease or trauma.
38. In **deep sleep** (*slow wave* or *non-REM sleep*), the body relaxes and cerebral cortex activity is low. In **rapid eye movement (REM) sleep**, active dreaming occurs. (Figure 16-10)
39. The **reticular activating system (RAS)**, a network in the reticular formation, is most important to arousal and the maintenance of consciousness. (Figure 16-11)
40. Changes in the normal balance between two or more neurotransmitters can profoundly affect brain function.

16-10 Aging produces various structural and functional changes in the nervous system

41. Age-related changes in the nervous system include a reduction in brain size and weight, a reduction in the number of neurons, a decrease in blood flow to the brain, changes in the synaptic organization of the brain, and intracellular and extracellular changes in CNS neurons.
42. The nervous system monitors all other systems and issues commands that adjust their activities. The efficiency of these activities typically decreases with aging. (Figure 16-12)

Review Questions

See the blue Answers tab at the back of the book.

LEVEL 1 Reviewing Facts and Terms

1. The preganglionic and ganglionic neurons are missing from the diagram below showing the distribution of sympathetic innervation. Indicate their distribution using red for the preganglionic neurons and black for the ganglionic neurons.

2. The autonomic division of the nervous system directs (a) voluntary motor activity, (b) conscious control of skeletal muscles, (c) unconscious control of skeletal muscles, (d) processes that maintain homeostasis, (e) sensory input from the skin.
3. The division of the ANS that stimulates visceral activity is the _____ division. (a) sympathetic, (b) parasympathetic, (c) craniosacral, (d) intramural, (e) somatomotor.
4. Effects produced by the sympathetic branch of the autonomic nervous system include (a) decreased heart rate and blood pressure, (b) lowered mental alertness, (c) increased digestive function, (d) decreased respiratory rate, (e) decreased urinary function.
5. Which of the following neurotransmitters is influenced by the antidepressant fluoxetine at the synaptic level? (a) norepinephrine, (b) dopamine, (c) serotonin, (d) amphetamine.
6. Starting in the spinal cord, trace an action potential through the sympathetic division of the ANS until it reaches a target organ in the abdominopelvic region.
7. Which organs can be innervated by parasympathetic nerves originating in the sacral segments of the spinal cord?
8. Distinguish between short and long visceral reflexes.
9. What cellular mechanisms identified in animal studies are thought to be involved in memory formation and storage?
10. What is the relation between the RAS and the cerebral cortex?
11. What anatomical and functional changes in the brain are linked to alterations that occur with aging?
12. All preganglionic autonomic fibers release _____ at their axon terminals, and the effects are always _____. (a) norepinephrine; inhibitory, (b) norepinephrine; excitatory, (c) acetylcholine; excitatory, (d) acetylcholine; inhibitory
13. In the sympathetic division of the ANS, beta receptors are located on the plasma membranes of cells in the (a) heart, (b) brain, (c) sweat glands, (d) arrector pili muscles.
14. Compare the effects of the sympathetic and parasympathetic divisions on the liver and pancreas.
15. Which three collateral ganglia serve as origins for ganglionic neurons that innervate organs or tissues in the abdominopelvic region?
16. How are two components of the skin controlled by the two divisions of the ANS?
17. Which four pairs of cranial nerves are associated with the cranial segment of the parasympathetic division of the ANS?
18. Which six plexuses in the thoracic and abdominopelvic cavities innervate visceral organs, and what are the effects of sympathetic versus parasympathetic stimulation?
19. What is the difference between sleep and coma?

LEVEL 2 Reviewing Concepts

20. Dual innervation refers to situations in which (a) vital organs receive instructions from both sympathetic and parasympathetic fibers, (b) the atria and ventricles of the heart receive autonomic stimulation from the same nerves, (c) sympathetic and parasympathetic fibers have similar effects, (d) all of these are correct.
21. Damage to the hippocampus, a component of the limbic system, leads to (a) a loss of emotion due to forgetfulness, (b) a loss of consciousness, (c) a loss of long-term memory, (d) an immediate loss of short-term memory.
22. Why does sympathetic function remain intact even when the anterior roots of the cervical spinal nerves are damaged?
23. The nerve branching from the sympathetic chain and containing sympathetic preganglionic fibers that end in the adrenal medulla is the (a) greater splanchnic nerve, (b) lesser splanchnic nerve, (c) lumbar splanchnic nerve, (d) sacral splanchnic nerve, (e) pelvic nerve.
24. Under which of the following circumstances would the heart rate be highest? (a) increased sympathetic stimulation, (b) decreased sympathetic stimulation, (c) increased parasympathetic stimulation, (d) decreased parasympathetic stimulation, (e) both increased parasympathetic and sympathetic stimulation.
25. A possible side effect of a drug used to open the airways of someone having an asthma attack is (a) decreased digestive system activity, (b) diarrhea, (c) profuse urination, (d) increased blood pressure, (e) decreased heart rate.
26. Being home alone at night and hearing breaking glass would likely affect a person. What physiological effects would this experience probably produce, and what would be their cause?
27. What are the different effects resulting from the stimulation of beta-1, beta-2, and beta-3 receptors, respectively?
28. Nicotine stimulates cholinergic receptors of the ANS. Based on this information, how would cigarette smoking affect the cardiovascular system?
29. The condition known as shock is characterized in part by a decreased return of venous blood to the heart. How could an upsetting situation, such as the sight of a tragic accident or very bad news, produce some temporary symptoms of shock?

LEVEL 3 Critical Thinking and Clinical Applications

30. Michael's sleep is seriously disturbed by his constant coughing. He complains about it to his physician. The doctor tells him coughing is a reflex in response to irritation of the respiratory tract. What kind of reflex is it?
31. While studying the activity of smooth muscle in blood vessels, Renata discovers that, when applied to a muscle plasma membrane, a molecule chemically similar to a neurotransmitter triggers an increase in intracellular calcium ions. Which neurotransmitter is the molecule mimicking, and to which receptors is it binding?

CLINICAL CASE Wrap-Up Remember Me?

Mabella has the progressive neurological disorder Alzheimer's disease. The hallmark of Alzheimer's disease is loss of memory. But patients also experience a gradual loss of cognitive functioning involving orientation, concentration, problem solving, judgment, and language. In the end stage, the person can no longer perform any activities of daily living and needs total care. This incurable disease can last for 5 or more years before the patient dies.

During life, the brain of a person with Alzheimer's disease is deficient in the neurotransmitter acetylcholine (ACh). Diagnosis is established by ruling out other causes of memory loss. On autopsy, Alzheimer's disease can be confirmed by an atrophied brain with wide sulci and shrunken gyri; under the microscope, abnormal plaques and neurofibrillary tangles that impair nerve transmission are evident.

1. If memory loss is her first symptom, what part of Mabella's brain is first affected? As her disease progresses, which additional brain regions become involved?
2. Mabella's doctor will check her mental orientation. A normal result is "oriented x3," which means the patient recognizes the three attributes of person, place, and time. In which order did Mabella lose her orientation as her disease worsened?
3. The doctor gave Mabella a trial of the drug donepezil, a cholinesterase inhibitor. Why did this help? Where specifically did the drug act?

See the blue Answers tab at the back of the book.

Related Clinical Terms

alpha₁-receptor agonists: Drugs used to treat hypotension (low blood pressure) by stimulating α_1 receptors to cause vasoconstriction of blood vessels.

alpha₂-receptor agonists: Drugs used to treat hypertension (high blood pressure) by stimulating α_2 -adrenergic receptors to inhibit sympathetic vasomotor centers.

beta-adrenergic blockers: Drugs that decrease heart rate and force of contraction, lowering peripheral blood pressure by acting on beta-adrenergic receptors to diminish the effects of epinephrine.

parasympathetic blocking agents: Drugs that target the muscarinic receptors at neuromuscular or neuroglandular junctions.

parasympathomimetic drugs: Drugs that mimic parasympathetic stimulation and increase the activity along the digestive tract.

sympathetic blocking agents: Drugs that bind to receptor sites, preventing a normal response to neurotransmitters or sympathomimetic drugs.

sympathomimetic drugs: Drugs that mimic the effects of sympathetic stimulation.

17

The Special Senses

Learning Outcomes

These Learning Outcomes correspond by number to this chapter's sections and indicate what you should be able to do after completing the chapter.

- 17-1 ■ Describe the sensory organs of smell, trace the olfactory pathways to their destinations in the brain, and explain the physiological basis of olfactory discrimination.
- 17-2 ■ Describe the sensory organs of taste, trace the gustatory pathways to their destinations in the brain, and explain the physiological basis of gustatory discrimination.
- 17-3 ■ Identify the internal and accessory structures of the eye and explain the functions of each.
- 17-4 ■ Describe how refraction and the focusing of light on the retina lead to vision.
- 17-5 ■ Explain color and depth perception, describe how light stimulates the production of nerve impulses, and trace the visual pathways to their destinations in the brain.
- 17-6 ■ Describe the structures of the external, middle, and internal ear, explain their roles in equilibrium and hearing, and trace the pathways for equilibrium and hearing to their destinations in the brain.

CLINICAL CASE

A Chance to See

Makena is a 12-year-old Kenyan girl living with her family in a small village in sub-Saharan Africa. Their village is miles away from roads, electricity, and health-care. Her family is very poor, and lives on less than \$1.25 per day. Makena's daily chores include walking 2 hours to collect water every morning before school and again after school. Water is so precious in this part of the world that nobody in Makena's village has ever taken a shower.

Makena is a bright girl, but she does not do well in school. She can't see the chalkboard in her classroom. She can't see the soccer ball when she tries to play with her classmates. She even has trouble seeing

the path that leads to the dry riverbed where she collects water from a deep hole. She has no idea that other people can see these things better.

No one in Makena's village wears eye-glasses, and most do not even know what they are. Makena's teacher, however, studied at the University of Nairobi and knows that glasses can correct vision problems. The teacher thinks perhaps nearsightedness is a problem for Makena. **Can a desperately poor child, many miles away from healthcare of any kind,**

obtain glasses to correct her poor vision? To find out, turn to the Clinical Case Wrap-Up at the end of the chapter.

17

An Introduction to the Special Senses
